Intertemporal Altruism[*]

Abstract

Most prosocial decisions involve intertemporal tradeoffs. Yet, the *timing* of prosocial utility flows is ambiguous and has largely disregarded in models of other-regarding preferences. We study the behavioral implications of the time structure of prosocial utility, leveraging a conceptual distinction between *consequence-dated* and *choice-dated* utility flows. We conduct a high-stakes donation experiment that comprehensively characterizes discounting behavior in self-other tradeoffs and allows us to identify different prosocial motives from their distinct time profiles. Our data can only be explained by a combination of choice- and consequence-dated prosocial utility. Both motives are pervasive and negatively correlated at the individual level.

Keywords: Altruism, Donation, Intertemporal Decision-Making, Time Inconsistency

1   Introduction

In prosocial decisions, choices and consequences are typically separated in time. Donations, for example, tend to create immediate costs to the donor and delayed benefits for others. Consider climate change charities, which routinely face the choice between promoting either adaptation or mitigation projects. The benefits from adaptation projects tend to accrue much earlier than those from mitigation projects. If individuals only care about the timing of the donation itself, then the different planning horizons of such projects should not affect their willingness to contribute. If, on the other hand, individuals do care about the timing of benefits, then charities are well-advised to take the different time frames into account. Consider instead a commitment to voluntary work where both the costs to the donor and the benefits to others are delayed. Similarly, repeated interactions such as reciprocal exchange also naturally involve intertemporal considerations. I may expect to reciprocate a favor from someone else later on, trading off an earlier benefit against a delayed cost. The inherent intertemporal nature of prosocial choices raises important questions about how choice environments affect the timing and level of prosocial choices and how we should think about the timing of the utility flows associated with prosocial decisions.

Notably, the existing theoretical literature on prosocial preferences largely abstracts from the time dimension of utility flows. For example, outcome-based models of inequity aversion do not specify how to evaluate inequality that occurs across two points in time (see, e.g. Fehr and Schmidt, 1999; Bolton and Ockenfels, 2000). To illustrate, consider a simple donation or dictator game with a delayed payment to the recipient. Do inequity-averse donors discount the corresponding recipient's utility in the same way as they discount their utility? Do their social preferences apply to the discounted utility stream (of self and recipient), or do they care about period-specific inequality? These timing-related considerations are not unique to inequity aversion, but apply to other forms of social preferences alike. In formal models of reciprocity (Charness and Rabin, 2002; Falk and Fischbacher, 2006; Dufwenberg and Kirchsteiger, 2004), social interactions are conceptualized as being inherently timeless. Returning a favor one year later is considered just as worthwhile as returning a favor now. From a different perspective, the

1

concept of warm glow (Andreoni, 1989, 1990) explicitly suggests that utility may derive from the act of choice itself rather than the prosocial externality. However, the corresponding theories do not distinguish between the timing of choice and delayed consequences. Similarly, models of image concern (e.g., Bénabou and Tirole, 2006) do not specify whether image utility accrues at the point of prosocial choice or at the time of its consequences or observability. The common practice of modeling prosocial behavior as *atemporal* limits our scope for understanding prosocial behavior in practice, which typically features a separation of choices and consequences over time as in the above examples. This gap in the literature calls for more discipline on the role of delays in theoretical and empirical work on prosocial behavior.

We provide a theoretically guided empirical investigation of discounting behavior in a high-stakes donation context. Unlike related empirical work, we do not focus on partial delays in dictator games (Dreber et al., 2016; Kovarik, 2009), the role of commitment (Breman, 2011; Rogers and Bazerman, 2008), or time inconsistency and present bias (Kölle and Wenner, 2018; Andreoni and Serra-Garcia, 2021). Instead, our experimental approach allows us to characterize entire discount functions in self-other trade-offs in a highly comprehensive and novel manner. Our analysis proceeds in three steps. First, we develop a conceptual distinction between *consequence-dated* and *choice-dated* utility in modeling intertemporal prosocial choice. This formal distinction leverages existing theoretical and empirical work in a productive fashion and provides a fruitful guiding framework for our own empirical exercise. If utility is consequence-dated, then it accrues with a delay that corresponds to when the actual utility consequences for others materialize. If utility is choice-dated, then it is realized in temporal proximity to the act of giving. We derive qualitative predictions of models with choice- and consequence-dated utility in different contexts. Second, we conduct a controlled laboratory study and establish a set of reduced-form patterns in atemporal and intertemporal donation behavior that directly speak to our model predictions. Third, we implement a structural model and estimate an explicit intertemporal utility function that reproduces the core patterns in our data and allows us to assess the relative importance of consequence-dated and choice-dated utility in determining prosocial behavior. Our experiment is deliberately designed to provide transparent identification of the different utility components (in

the spirit of, e.g., DellaVigna, 2018).

To experimentally study the intertemporal dimension of prosocial choice in a meaningful way, we implement a choice paradigm with far-ranging real-world implications. In our incentivized, high-stakes donation paradigm, each participant could save human lives by individually causing donations of up to 800 euros for the treatment of tuberculosis patients by a designated charity and earn up to 200 euros for themselves. The unusually high incentives serve to make both the donation context and the implemented delays meaningful to subjects. For all choice tasks, we use a variant of the widely used multiple price list methodology. The experiment comprises two parts: a series of intertemporal choice tasks in which participants decide between dated certain payments to themselves or the charity for delays of up to twelve months, and a series of atemporal risky choice tasks to characterize participants' multi-attribute utility function representing preferences over "self-euros" and "charity-euros." The first part is further divided into three stages. Across stages, we vary whether choices present (a) trade-offs between earlier and later payments in a single utility domain (only self-euros or only charity-euros), (b) trade-offs between payments in different domains that involve a unique, common payment date either now or in the future, and (c) trade-offs across domains and payment dates that require self-other comparisons across time. This setup systematically examines behavior when either (a) only time matters, (b) only cross-attribute comparisons matter, or (c) both time and cross-attribute comparisons matter. To our knowledge, this is the first experiment providing data that are rich enough to allow for sharp tests of the discounted utility model in the multi-attribute case of self-other tradeoffs.

We purposefully opted for a design with monetary pay-offs because (i) *prosocial* utility flows are not typically associated with primary consumption by the decision-maker such as food or effort; (ii) we aim to characterize discount functions comprehensively, including for time horizons in excess of one month, which has not been accomplished with real-effort designs so far;[1] and (iii) our interest is partly in the application to monetary donations, which is the most widespread form of altruistic behavior in practice and has immedi-

---

[1]Real effort experiments have been conducted for short-time horizons of up to a few weeks for logistical reasons that mainly concern trust issues and attrition (Augenblick, 2019; Augenblick and Rabin, 2018).

ate consequences for charities. The recent methodological review by Cohen et al. (2019) discusses situations in which money designs may be preferable to real-effort paradigms, which we argue includes our case of studying prosocial utility flows that are typically not yoked to primary consumption by the decision-maker.[2] Our design deliberately abstracts from the issue of present bias and the phenomenon of extreme short-run impatience by implementing payments as wire transfers. Even the soonest possible experimental payment was subject to a delay of three days, which the literature conventionally considers as being "in the future."[3]

We start with a discussion of our reduced-form findings and document non-parametric evidence compatible with consequence-dated as well as choice-dated prosocial utility. First, in smaller-sooner, larger-later choices involving either only self-euros or only charity-euros, subjects discount both delayed self-euro and delayed charity-euro payments. The notion that delayed donations are less valuable to subjects implies that valuations of charity-euros are linked to their payment date, pointing towards the existence of a consequence-dated component of prosocial utility flows. This qualitative devaluation pattern of delayed donations obtains for *all* intertemporal decisions that involve a time trade-off between the two choice options, including cross-attribute intertemporal decisions. More strikingly, net present values measured for delayed self-euros and delayed charity-euros are statistically indistinguishable. Non-parametric analyses imply that our combined data from atemporal choices and choices involving time trade-offs are specifically in line with the discounted utility specification of consequence-dated utility, i.e., an intertemporal utility function that applies the same discount function to future utility streams generated by self-euro and charity-euro payments. Second, how-

---

[2]Outside of the topic of other-regarding preferences, it has been pointed out that money designs may confound the timing of payments with the timing of primary consumption (Cubitt and Read, 2007; Chabris et al., 2008). The emergent view in this literature may be that subjects tend to treat money like consumption (perhaps due to narrow bracketing), except in very short-time horizons (Cohen et al., 2019; Augenblick, 2019; Halevy, 2015; Balakrishnan et al., 2020).

[3]There are alternative methodologies, including the recent innovation of convex time budgets (Andreoni and Sprenger, 2012). While convex time budgets do not require a separate estimation of the utility function, we prefer the "double multiple price list" method of characterizing the atemporal utility function using separate choices (e.g. Andersen et al., 2008). In so doing, we can examine the features of the multi-attribute atemporal utility function in more detail and circumvent the issue of bunching at the boundaries and choice inconsistencies frequently observed with convex time budgets (Chakraborty et al., 2017).

ever, when contemporaneous, identically-dated self-euro and charity-euro payments are delayed into the future, subjects become increasingly more willing to give up self-euros for charity-euros as the delay increases. These choices that create a cross-attribute but no time trade-off imply a declining subjective exchange rate between charity-euros and self-euros. To our knowledge, we provide the first dataset that allows documenting such a pattern based on experimental variation. This finding is incompatible with a stationary flow utility function as posited by the discounted utility model where identically-dated utility flows are subject to the same discount factor. Under those circumstances, the effect of discounting cancels out, and we expect a constant exchange rate. Instead, our finding of a declining forward exchange rate suggests that the prosocial utility derived from donating money has a choice-dated component that is not subject to discounting due to, for example, warm glow or self-image concerns. We can only rationalize a declining subjective exchange rate if prosocial utility from donating (partly) accrues at the time of choice and is independent of the timing of the actual payment. Hence, our reduced-form findings suggest both a consequence-dated and a choice-dated component of prosocial utility. However, none of the existing models of prosocial behavior are compatible with this combination of motives.

We fill this gap and develop a simple model of intertemporal prosocial choice that accommodates both consequence-dated and choice-dated prosocial utility flows. We fit this model to our data using structural estimations at both the population and subject level. Our structural analysis adds two insights. First, our estimated structural model replicates the distinctive choice patterns identified in our reduced-form analysis. Most importantly, we are able to replicate a declining forward exchange rate because the relative weight of choice-dated utility in the discounted prosocial utility increases. As choice-dated utility is not discounted, the overall prosocial utility thus declines less quickly in the delay than the discounted utility from equally-delayed self-euros. Our parameter estimates for standard preferences parameters are in line with previous work. Second, the structural analysis sheds light on the individual-level variation of parameters, revealing that the different forms of prosociality display marked heterogeneity. We find that 80% of subjects exhibit meaningful, positive consequence-dated prosociality, and just below

5

60% of subjects show meaningful, positive choice-dated prosociality. Strikingly, there is a strong negative correlation between the two parameters at the subject level. This negative relationship indicates that differently-dated prosocial motivations might characterize distinct "types" of subjects. Some are primarily driven by consequence-dated motives such as pure altruism, whereas others seem to follow choice-date motivations such as image concerns or the feeling of warm glow.

We build on and contribute to several stands of the literature. Our conceptual distinction between consequence-dated and choice-dated prosocial motives complements existing research on what motivates contributions to public goods and charitable giving. While departing from existing work in terms of our focus on the time dimension rather than – for example – the impact of one's generosity and the corresponding "neutrality" hypothesis (Andreoni, 1989), we view the distinction drawn here as a natural extension and re-interpretation of the work on warm glow and pure altruism. Focusing exclusively on intertemporal arguments leads us to conclude the existence of mixtures of both motives, which resonates with previous work that documents mixed motivations, i.e. "impure altruism" (Andreoni, 1993; Bolton and Katok, 1998; Konow, 2010).[4] The distinction between choice-dated and consequence-dated prosocial utility provides a productive framework to extend models of prosocial behavior to an intertemporal context. It predicts that the primary motivation for prosocial behavior *changes* with the temporal delay. While considerations of consequence will be more important when they are realized in temporal proximity, the choice-dated component of prosocial utility will drive choices involving consequences that are strongly separated in time. This *switch* implies that simply extrapolating previous evidence on the relative importance of different prosocial motives from atemporal contexts to intertemporal settings may lead to inaccurate conclusions.

We also provide the first comprehensive experimental dataset on intertemporal prosocial behavior using a fully-crossed design of choices involving single vs. cross-attribute trade-offs – self-euro vs. charity-euro payments – and short vs. long delays. The concept of a "forward exchange rate" characterizes

---

[4]Moreover, our finding of correlation aversion – i.e., that the marginal utilities of self-euro and charity-euro payments are not independent - leads to the substantive interpretation that own earnings and donations are partial substitutes. This underscores the emerging consensus on a relationship between income, wealth, and charitable giving (Meer and Priday, 2020).

behavior for increasing, *common* delays, which provides a non-parametric test of the discounted utility model. Accordingly, our experimental approach allows us to address questions about the nature of intertemporal prosocial trade-offs that cannot be answered with a subset of this data. Previous empirical research has focused on different aspects of intertemporal self-other tradeoffs as outlined above (Dreber et al., 2016; Kovarik, 2009; Breman, 2011; Rogers and Bazerman, 2008; Kölle and Wenner, 2018; Andreoni and Serra-Garcia, 2021). While our account rationalizes some of this evidence through the implied time patterns of flow utility rather than, e.g., a hyperbolic shape of the discount function, we view our work as fruitfully complementing this emerging body of evidence that has different objectives and focuses on different phenomena such as time inconsistency and present bias.

Additionally, our findings inform work on intertemporal multi-attribute utility more generally. The literature has only recently started to explore the ramifications of multi-attribute utility functions for modeling intertemporal choice (Andersen et al., 2018). Although related empirical work studies the patterns of multi-attribute, intertemporal choices (Cubitt et al., 2018), it only looks at typical consumption goods rather than self-other trade-offs and – unlike our paper – does not quantify the effects using structural estimation. While our results from single-domain discounting choices are in line with a unique, domain-general discount function, which is a key assumption of the discounted utility model, previous studies report discounting patterns that sometimes differ across goods (Chapman, 1996; Frederick, 2006; Hardisty and Weber, 2009; Kim et al., 2013; McClure et al., 2007). These studies have different objectives from ours, and consequently, they do not separately account for the shape of the atemporal utility function and do not rely on high-stakes experimental designs.

The paper proceeds as follows. Section 2 lays out a theoretical framework for our argument. Section 3 describes the experimental design and procedures. We present our reduced-form results in Section 4 and the structural analyses in Section 5. Finally, Section 6 concludes.

2 Conceptual framework

We develop a simple formal framework that is not intended as an exhaustive theoretical characterization of intertemporal prosocial choice and that we do not consider a main contribution of the paper. Instead, the objective of this section is twofold: first, it carves out our main conceptual distinction between consequence- and choice-dated utility flows in a tractable and easily generalizable fashion. Second, the framework disciplines and guides our subsequent empirical analysis.

Standard theory assumes that individuals derive utility from the consumption of goods and services. However, prosocial choices such as donations are usually not associated with primary rewards and require additional assumptions about the sources of utility. Consequently, research in psychology allows for a broader notion of consumption that is not limited to physical consumption but instead involves forms of conceptual consumption that occur entirely in the mind (Ariely and Norton, 2009; Schelling, 1988). In line with this approach, the economic literature on prosocial preferences puts forward a variety of motives such as intentions (Falk and Fischbacher, 2006) or image concerns (Bénabou and Tirole, 2006) that are independent of immediate consumption by the decision-maker. This variety of prosocial motivations naturally lends itself to distinguish between the time structures of corresponding utility flows. We apply the canonical notion of dated period utility from intertemporal choice theory but disentangle two constituent elements of prosocial behavior. We introduce an explicit distinction between the act of making a prosocial choice and the consequences of this choice for others. In this framework, we refer to utility flows as *choice-dated* if they are realized at the time of giving and as *consequence-dated* if they accrue when the consequences for others actually materialize.

We seek to understand what this conceptual distinction implies for intertemporal prosocial choice and what we can learn from observed choices about the nature of prosocial preferences. In a first step, we address these questions and discuss the implications of models in which decision-makers receive *only* consequence-dated prosocial utility or *only* choice-dated prosocial utility. Our setting is deliberately simplified as we explore the two extreme cases to explore and contrast their distinct implications. In a second step, we

consider the mixed case where both types of prosocial utility are present.

Let t index the current period in which a choice is made, and τ denote the time relative to the choice period. Let $x_{t+\tau}$ represent a dated payment to the decision-maker at time $t + \tau$ ("self-euros"). Moreover, let $g_{t+\tau}$ denote a dated payment to a charity at time $t+\tau$ ("charity-euros"). The decision-maker has preferences over dated payment streams $z = (x_{t+\tau}, g_{t+\tau})_{\tau \in \mathbb{N}}$ represented by an intertemporal utility function $U(z)$. We do not assume a specific form of prosocial preferences at this stage and treat self-euros $x_{t+\tau}$ and charity-euros $g_{t+\tau}$ as direct inputs to the utility function. In line with the previous literature (Balakrishnan et al., 2020; Halevy, 2015), payment dates serve as a proxy for the conversion of money into utility for the self or others or as (sufficiently delayed) monetary payments treated as consumption goods. To simplify the following analysis, we interpret payment dates as representing the corresponding consumption dates.

We specify payments to others as a direct input into the utility function of the decision-maker. This approach is consistent with the interpretation that the decision-maker's prosocial utility truly depends on the utility – rather than the pay-off – consequences for others. Our conclusions remain unchanged as long as the recipient's utility is monotonic in the payments that they receive and approximated in time by the payment dates. Thus, we refrain from specifying the recipient's utility function for simplicity.[5]

In the spirit of providing conceptual guidance for our experimental study, we now separately discuss the concepts and psychological motivations of consequence-dated and choice-dated utility separately before contrasting their empirical predictions.

2.1   Consequence-dated prosocial utility

In the case of consequence-dated prosocial utility, the utility of a donation to charity $g_{t+\tau}$ at time $t + \tau$ will also accrue at $t + \tau$, even if caused by a choice at an earlier point in time t. In this case, choosing between two dated payments to a charity with different payment dates requires an intertemporal comparison of prosocial utility flows. We can draw on standard economic

---

[5]If we assume that the other person's utility is – ceteris paribus – a monotone function $v(g)$ of donations, we can substitute $v(g)$ for g in the utility function and study the reduced form.

tools and assume that the decision-maker behaves as if she maximizes her discounted intertemporal utility. The following intertemporal utility function then characterizes models of consequence-dated prosocial utility:

$$U_t = \sum_{\tau=0}^{T} D(\tau)u(x_{t+\tau}, g_{t+\tau}). \tag{1}$$

We make the standard assumptions that there is a stationary discount function $D(\tau)$ that applies to future utility flows (Cohen et al., 2019). The flows are represented by a stationary flow utility function, $u(x_{t+\tau}, g_{t+\tau})$, which captures the decision-maker's concern for herself and others.

Two remarks about this specification are in order. First, while we remain deliberately neutral about the precise psychological motives underlying consequence-dated prosocial utility, pure altruism provides a natural interpretation of Equation (1). A pure altruist cares about the welfare consequences of their choices, which in the model is determined by $g_{t+\tau}$. Any self-other trade-off then involves interpersonal utility comparisons, suggesting the interpretation of u as the decision-maker's subjective welfare function for evaluating contemporaneous consequences of her choices to the self and others. Second, a complementary perspective on the intertemporal utility function in Equation (1) is the natural extension of the workhorse model of intertemporal choice – discounted utility – to the multi-attribute case, because it conceptualizes self-euros and charity-euros as conventional arguments of a flow utility function. Consequently, the interpretation of prosocial behavior in an intertemporal context through the lens of multi-attribute discounted utility is akin to adopting the perspective of consequence-dated prosocial utility.

2.2 Choice-dated prosocial utility

In the case of choice-dated prosocial utility, the utility of a dated donation $g_{t+\tau}$ accrues in the period t in which it was caused through a choice, even if the payment is executed at a later date $t+\tau$. This implies that earlier and later donations to charity generate the same utility to the decision-maker. It introduces a theoretical distinction between consequence-dated and choice-dated

10

prosocial utility that allows us to obtain sharp qualitative descriptions.[6] We can then represent choice-dated prosocial utility with the following intertemporal utility function:

$$U_t = \sum_{\tau=0}^{T} \alpha(g_{t+\tau}) + \sum_{\tau=0}^{T} D(\tau) u(x_{t+\tau}), \tag{2}$$

where $\alpha(g_{t+\tau})$ is the choice-dated and immediate prosocial utility that results from causing a potentially delayed donation today. Note that for our illustrative purposes here, we rule out complementarities between self-euros and charity-euros as well as interactions between choice-dated utility derived from actions with consequences that materialize with different delays.[7] Again, we do not take a stance on the psychological motives of choice-dated utility and its specific relationship to the size of a donation. However, our formulation naturally encompasses a wide range of motives. They include the feeling of warm glow that is explicitly defined as being related to the act of giving (Andreoni, 1989, 1990) and self- or social-image concerns that are routinely characterized as being linked in time to the act of donating rather than to the instrumental value of charitable funds.

2.3 Qualitative predictions

We contrast the implications of models of choice-dated and consequence-dated prosocial utility for intertemporal choices involving self-euros and charity-euros.

In Figure 1, each axis represents one of the following three trade-offs: (1) pure time trade-offs (univariate discounting, UD_τ), (2) pure across-domain trade-offs (subjective exchange rates, F_τ) and (3) mixed across-time and across-domain trade-offs (multivariate discounting, MD_τ).[8]

---

[6]It is possible that delayed donations provide lower choice-dated prosocial utility. However, choice-dated prosocial utility should devalue at a *lower rate* than consequence-dated utility, as it is otherwise indistinguishable from consequence-dated considerations. This means that as the delay increases, the prosocial motivation in choice-dated models will be relatively more stable compared to the prosocial motivation in consequence-dated models. Our results only require this *relative* property. To simplify the exposition, we directly assume
Figure 1: This figure displays three intertemporal self-other trade-offs.

We begin with the horizontal axes in Figure 1, which capture the standard case of univariate discounting (UD_τ). A decision-maker can choose between receiving m_t charity-euros (self-euros) at time t or receiving a larger payment of $m_{t+\tau}$ charity-euros (self-euros) at a later time $t + \tau$. The prediction of consequence-dated prosocial utility is that the value of charity-euros (self-euros) decreases by $D(\tau)$ with the additional delay τ. While choice-dated prosocial utility necessarily makes the same qualitative prediction for univariate discounting of self-euros, the immediate gratification from giving other-euros to charity is not subject to discounting.

Prediction 1. *Delayed charity-euros are discounted in consequence-dated models, but not in choice-dated models, of prosocial behavior. Both models predict discounting of delayed self-euros.*

Next, we turn to the vertical axes in Figure 1 and consider the exchange rate F_τ, which describes the decision-maker's subjective conversion rate be-

---

that choice-dated utility is independent of the delay.

[7] One could accommodate these complementarities using more general classes of utility functions such as $U_t = V(W(a) + b)$ where a and b represents the two sums in Equation (2).

[8] In Appendix C, we discuss the case of choice-dated prosocial utility more extensively under weaker assumptions and obtain qualitatively similar predictions.

tween contemporaneous self-euros and charity-euros in τ periods. It is defined as $F_\tau = g^*_{t+\tau}/x_{t+\tau}$ whenever the decision-maker is indifferent between $g^*_{t+\tau}$ and $x_{t+\tau}$.[9] In a choice-dated model, the corresponding indifference condition is

$$D(\tau)u(x_{t+\tau},0) = D(\tau)u(0,g^*_{t+\tau}). \tag{3}$$

As the discount factor $D(\tau)$ cancels from this expression, the exchange rate F_τ does not depend on τ. Note that this holds irrespective of the shape of the flow utility function, providing the distinctive prediction of a constant exchange rate for models of consequence-dated prosocial utility. By contrast, in models of choice-dated prosocial utility, the defining equation of the exchange rate takes the following form:

$$D(\tau)u(x_{t+\tau}) = \alpha(g^*_{t+\tau}). \tag{4}$$

As the delay τ of both payments increases, the decision-maker discounts the value of self-euros on the left-hand side, while the choice-dated prosocial utility remains unaffected. Thus, $g^*_{t+\tau}$ decreases, causing the exchange rate F_τ to decrease in τ.

Prediction 2. *Consequence-dated models predict a constant exchange rate, whereas choice-dated models of prosocial behavior predict a declining exchange rate.*

Finally, we turn to the diagonal axes in Figure 1, which capture multivariate discounting (MD_τ). Similar to the exchange rate, this intertemporal trade-off only arises in the multi-attribute case. A decision-maker receives m_t self-euros (charity-euros) at time t and is then asked to state the dated payment $m_{t+\tau}$ of charity-euros (self-euros) to be received at a later time $t+\tau$ that makes her indifferent. This decision involves a choice between payments to different recipients at different points in time, and provides an implicit multivariate discount factor of $m_t/m_{t+\tau}$. As in the case of univariate discounting, consequence-dated models will discount the value of the later payment, irrespective of whether it is denominated in self-euros or charity-euros. In both cases, we expect to see multivariate discounting. If the earlier payment involves self-euros, the indifference condition is $u(m_t,0) = D(\tau)u(0,m_{t+\tau})$.

---

[9]The exchange rate will depend on the level of payments unless the utility function satisfies homogeneity, but we omit the dependence for ease of exposition.

The right-hand side decreases with τ, while the left-hand side is constant, causing multivariate discounting. In the other case, we have the symmetric condition $u(0, m_t) = D(\tau)u(m_{t+\tau}, 0)$. For models of choice-dated prosocial utility, we obtain the same prediction of multivariate discounting only when the early payment is denoted in charity-euros, because then the value of delayed self-euros is also discounted. However, we expect no multivariate discounting if the early payment involves self-euros. The reason is again that the immediate, choice-dated prosocial utility is unaffected by the delay τ of charity-euros. The indifference condition is as follows:

$$u(m_t, 0) = \alpha(m_{t+\tau}).$$

Prediction 3. *Consequence-dated models predict multivariate discounting, whereas choice-dated models of prosocial behavior predict multivariate discounting if the later payment involves self-euros and no multivariate discounting if the later payment involves charity-euros.*

Figure 1 summarizes the predictions that we now explore in our tailored experimental setting. It is straightforward to obtain qualitative predictions for the mixed case of both choice-dated and consequence-dated prosocial utility.

Table 1: Predictions of different models

	Type of prosocial utility		
Prediction	Choice-dated	Consequence-dated	Both
Univariate discounting of self- and charity-euros		✓	✓
Declining exchange rate	✓		✓
Multivariate discounting for both self- and charity-euros as today's numeraire		✓	✓

3   Experimental design and procedures

We set up a tightly controlled experiment that allows the precise manipulation of payment dates, including a credible implementation of future payments

and donations. At the same time, the stakes remain quantitatively meaningful even when payments are delayed substantially.

3.1 Saving a Life donation paradigm

To make delays in experimental outcomes relevant to subjects, our design attempts to take prosocial decision-making in a controlled setting to the limits: we developed a high-stakes donation paradigm in cooperation with the Indian non-profit organization Operation ASHA, which specializes in the treatment of tuberculosis, the world's deadliest bacterial infectious disease (World Health Organization, 2020).[10] Operation ASHA's model for treating tuberculosis has received extensive public acclaim and worldwide media coverage. Under conservative assumptions, a donation of 350 euros – roughly 400 US dollars at the time – covered all costs incurred by Operation ASHA to identify, treat and cure five patients, which is equivalent to saving one additional human life in expectation.[11]

Our experimental instructions provided detailed information about the causes, prevalence, and implications of tuberculosis and Operation ASHA.[12] All information on tuberculosis was verifiable and came from acknowledged sources, in particular the *World Health Organization*. We directly transferred all donations to Operation ASHA's bank account on the exact day specified in the experiment and offered subjects the opportunity to inspect proof of the bank transfer.

3.2 Design

The experiment comprises two consecutive parts: intertemporal choices (Part A) and atemporal choices under risk (Part B). Across both parts of the experiment, each subject completed a total of 36 decision screens, 21 involving intertemporal choices and 15 involving choices under risk. In each part, one

---

[10]See Operation ASHA's website at `http://www.opasha.org` for details.

[11]We estimated the all-inclusive cost of a life saved by Operation ASHA based on public information on the charity's operations in combination with estimates from peer-reviewed epidemiological studies on tuberculosis mortality (Straetemans et al., 2011; Tiemersma et al., 2011; Kolappan et al., 2008). We conferred our donations as a restricted grant ensuring that no money is used to cover overhead costs and that the donations flow immediately into scaling up the Operation ASHA's treatment model.

[12]See our experimental instructions in the Appendix.

randomly-chosen row of the price list on a randomly-chosen decision screen was selected by the computer and added to the subject's earnings. Before we provide the implementation details on both parts, two general remarks about the experimental design are in order.

First, we implement choices involving monetary payments to the subjects and the charity, rather than primary consumption such as effort or food. While most research on discounting behavior has relied on financial rewards, the recent experimental literature emphasizes that the discounted utility model posits discounting of *utility*, and that monetary payments only enter utility via primary consumption. Cohen et al. (2019) review this literature and conclude that studies using financial flows tend to find lower discount rates and a less hyperbolic discount function, implying smaller present bias. In the present study on self-other trade-offs in the context of donations, we use monetary payments, because most donations in practice are denominated in money. Our interest lies in time horizons exceeding two months, which has previously not been studied using primary consumption due to the logistical complications. Furthermore, we aim to circumvent the issue of genuine present bias to identify choice-related utility flows. The differences between discounting of financial flows and primary consumption are most pronounced for very early rewards, and previous work has argued that monetary rewards that do not occur in the immediate future are treated as consumption (Augenblick, 2019; Halevy, 2015; Balakrishnan et al., 2020). Building on this debate, our deliberate design choice of avoiding utility consequences from consumption "in the present" allows for the simplifying assumption that delayed payments directly enter the utility function. In our setting, even the earliest payment date in our experiment lies "in the future". Specifically, we execute payments as bank transfers, with the earliest payment being available to subjects no sooner than three days following the day of the experiment.

Second, we use the widely-established multiple price list method for all intertemporal and risky choice tasks (Attema et al., 2016; Holt and Laury, 2002; Schubert et al., 1999; Dohmen et al., 2017). On each decision screen, subjects faced a list of binary decisions between a fixed left-hand-side amount and a right-hand-side option with increasing amounts from the top to the bottom of the list. It is well established in the intertemporal choice literature that estimates of discount rates from simple "money earlier versus later" choices alone

are confounded given pervasive evidence against linear utility even for small amounts. Several approaches address this issue (Montiel Olea and Strzalecki, 2014; Ericson and Noor, 2015), including the recently popular paradigm of convex time budgets, which does not require a separate elicitation of the utility curvature (Andreoni and Sprenger, 2012). We instead rely on the "double price list method", which estimates the shape of the atemporal utility function from separate risky choices, extending the approach of Andersen et al. (2008) to the multi-attribute case. While both methods have been shown to perform well in practice (Andreoni et al., 2015), we primarily resort to using separate risky choices due to our objective of precisely characterizing the multi-attribute atemporal utility function.[13]

3.2.1 Part A – Intertemporal choices

We study intertemporal choices involving payments of self-euros and charity-euros by implementing a fully-crossed design with decisions involving cross-attribute vs. no cross-attribute trade-offs and differential delays vs. no differential delays. Using multiple price lists as shown in Appendix Figure A.1, we elicit indifference points between certain self-euro or charity-euro payments at different, exactly-specified delays. Part A comprises five stages presented in randomized order.

Univariate discounting includes two stages, *UD – SELF* and *UD – CHARITY*, in which we separately elicit net present values of delayed payments of self-euros or charity-euros, respectively. On each decision screen of stage *UD – SELF*, subjects face a list of binary choices between a fixed payment of 50 self-euros to be received by bank transfer at the earliest possible payment date after three days and increasing amounts of self-euros at a fixed later point in time. The delay of the later payment varies across decision screens and may be either 1, 3, 6, or 12 months, in randomized order. Subjects complete four decision screens in stage *UD – SELF*. Stage *UD – CHARITY* is identical to *UD*

---

[13]Note that both methods have practical disadvantages. While choices from convex time budgets produce substantial bunching at the boundaries and choice inconsistencies (Chakraborty et al., 2017), the price list methodology creates a substantial minority of subjects who switch multiple times in a single list, which is at odds with monotonic preferences (e.g. Bruner, 2011). Here we circumvent the complications associated with multiple switching points in the data by enforcing a unique switching point. This was implemented using an auto-completion function that filled in remaining choices as soon as a subject switched from the fixed left-hand-side option to the increasing right-hand-side option.

– *SELF* except that both the earlier and later payments involve donations to charity, which would be made by bank transfer on the specified dates in a way that could be verified by subjects later on. In our univariate discounting choices, individuals face a trade-off between two payments for the *same* recipient (either self-euros or charity-euros) that occur at *different* points in time.

We measure subjective exchange rates between self-euro and charity-euro payments at different points in time in stage *ER*. On each decision screen, subjects face a list of binary choices between a payment of 50 self-euros at a specified point in time and increasing amounts of charity-euros at the *same* point in time. Time points include bank transfers to be expected with the shortest delay of three days (the *spot exchange rate*) as well as in 1, 3, 6, or 12 months (*forward exchange rates*). These five decision screens provide measures of how many charity-euros subjects demand per contemporaneous self-euro for different delays from today's perspective. Note that the choices about the subjective exchange rate present individuals with trade-offs between two payments for *different* recipients, but occurring at the *same* points in time.

We measure trade-offs between two payments – one denominated in self-euros and one in charity-euros – with different delays. Stages *MD – SELF* and *MD – CHARITY* thus capture the common situation in which individuals face trade-offs between giving and taking, but the corresponding payment flows occur at different times. On each decision screen in stage *MD – SELF*, subjects face a list of binary choices between a fixed payment of 50 self-euros at the earliest delay and increasing amounts of charity-euros at a fixed later point in time. Conversely, in stage *MD – CHARITY*, subjects face a list of binary choices between a fixed payment of 50 charity-euros at the earliest delay and increasing amounts of self-euros at a fixed later point in time. As before, the later time points include 1, 3, 6 and 12 months. Multivariate discounting choices create trade-offs between two payments for *different* recipients, occurring at *different* points in time.

Within Part A, both the order in which stages occur and the order of decisions within each stage are randomized at the individual level.[14] Right-hand-side options in the price lists range from a simple annualized discount rate of

---

[14]To avoid confusion, all decision screens belonging to the same stage appeared consecutively (in randomized order).

0% to 150% in increments of five percentage points for univariate discounting, from zero euros to 200 euros in increments of 10 euros for the exchange rates, and from zero euros to an annualized discount rate of 150% (relative to the 50 euros left-hand-side option) in 25 steps in stages *MD – CHARITY* and *MD – SELF*.

3.2.2 Part B – Risk apportionment

The objective of Part B is to characterize individuals' multi-attribute utility functions using atemporal decisions, i.e. choices that do not involve differently-dated payments. Note that the intertemporal choices in Part A only identify discounting behavior under the assumptions that flow utility is linear and additively separable in its attributes.

We adopt the recently popularized experimental paradigm of risk apportionment, which allows for non-parametric testing conditions on the nature of the utility function. Second- and third-order risk aversion (i.e. prudence) are typically defined in terms of specific conditions on the (second and third) derivatives of the utility function under expected utility maximization. Eeckhoudt and Schlesinger (2006) provide an alternative definition based on observable choices in risk apportionment tasks. Risk apportioning has the desirable feature that the measurement remains valid even if expected utility theory fails (Ebert and van de Kuilen, 2015; Starmer, 2000). At the same time, data from risk apportionment choices allow us to calibrate specific utility specifications under additional parametric assumptions.

We measured univariate risk aversion individually for self-euros and for charity-euros (stages *RA – SELF* and *RA – CHARITY*, respectively), univariate prudence (stages *PR – SELF* and *PR – CHARITY*), and multivariate risk aversion (stage *X – RA*). The latter stage is crucial as it delivers a non-parametric estimate of *correlation aversion* (Richard, 1975; Epstein and Tanny, 1980), which is a sufficient condition for assuming additive non-separability of the utility function.

In every risk apportionment task, subjects receive some endowment $\mathbf{e} = (x, y)$ of attributes X and Y and then make a decision between two lotteries. Each of these lotteries has two equally likely outcomes. Assume further that there are two undesirable fixed amounts R_1 and R_2 with $R_i \preceq (0, 0)$. Accord-

ingly, R_1 is a fixed univariate "reduction" in either X or Y, but not in both dimensions at the same time.[15] A preference for risk apportionment is the desire to disaggregate these unavoidable fixed reductions in wealth, R_1 and R_2, across two equiprobable states of the world, as depicted in Figure 2.

$$\mathscr{A} \begin{array}{c} \nearrow^{1\backslash 2} \mathbf{e} + R_1 \\ \searrow_{1\!\!/2} \mathbf{e} + R_2 \end{array} \qquad \succeq \qquad \mathscr{B} \begin{array}{c} \nearrow^{1\backslash 2} \mathbf{e} + R_1 + R_2 \\ \searrow_{1\!\!/2} \mathbf{e} \end{array}$$
Figure 2: Preference for risk apportionment (cf. Ebert and van de Kuilen (2015))

The different stages in Part B vary depending on whether each attribute (X and Y) corresponds to self-euros or charity-euros. Concretely, we present subjects with choices between two lotteries as summarized in Figure 2. For conceptual consistency and to avoid confusing subjects, we employ the same price list methodology as for intertemporal choices in Part A.[16] On each decision screen, subjects make binary choices between a fixed lottery $\mathscr{A}$ and a fixed lottery $\mathscr{B}$, where an additional, state-independent compensation payment m is added to lottery $\mathscr{B}$. This compensation payment m gradually increases across the rows of the choice list. The smallest amount for which the individual prefers lottery $\mathscr{B}$ indicates the minimal compensation demanded for heaving both undesirable reductions in wealth clustered in a single state. An example choice screen is depicted in Appendix Figure A.2.

Table 2 shows all fifteen choice scenarios presented to subjects. Note that for our measure of prudence, R_2 is a zero-mean lottery instead of a fixed reduction in wealth, i.e. R_2 only adds variance in this case. The grid of compensations offered in the choice lists varies with the endowments. Each choice list contains 21 rows across which the compensation increases at equal intervals. All grids are centered at zero.

---

[15]The same holds for R_2, but R_1 and R_2 do not necessarily affect the same attribute.

[16]Concretely, our design extends the procedure suggested in Ebert and Wiesen (2014) to a multi-attribute setting.

Table 2: Overview of risk apportionment choices

Stage	Endowment		R$_1$		R$_2$		Expected value	
	Self	Charity	Self	Charity	Self	Charity	Self	Charity
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)
RA – SELF	25		-10		-5		17.5	
	50		-20		-10		35	
	100		-40		-20		70	
PR – SELF	40		-10		(14, 0.5; -14, 0.5)		35	
	40		-10		(7, 0.8; -28, 0.2)		35	
	40		-10		(-7, 0.8; 28, 0.2)		35	
RA – CHARITY		25		-10		-5		17.5
		50		-20		-10		35
		100		-40		-20		70
PR – CHARITY		40		-10		(14, 0.5; -14, 0.5)		35
		40		-10		(7, 0.8; -28, 0.2)		35
		40		-10		(-7, 0.8; 28, 0.2)		35
X – RA	25	25	-10			-10	20	20
	50	50	-20			-20	40	40
	100	100	-40			-40	80	80

Note: All values are displayed in euros. Columns labeled "Self" indicate payments to the subject and columns labeled "Charity" indicate payments to the charity. If R_1 or R_2 is a non-degenerate lottery, it is given as $(x_1, p_1; x_2, p_2)$, where x_i indicates the amount and p_i the probability of receiving it. Columns 8 and 9 show the expected payment to the subject and the expected payment to the charity, respectively.

3.2.3 Procedures

We recruited 244 subjects from the student subject pool of the *BonnEconLab* at the University of Bonn. Table A.1 provides summary statistics for the full sample. The experiment was conducted in the main auditorium at the University of Bonn. We collected data in nine sessions from September 19 to September 22, 2016. The experiment was fully computerized and conducted using the software oTree (Chen et al., 2016). Subjects were seated in separate cubicles to create full privacy so that no other person could see their screen during the experiment. They could ask questions to an experimenter at any time. The average completion time was 65 minutes.

Subjects received a fixed amount of five euros for their participation in the experiment. All payments were made as bank transfers initiated on the precise day indicated for the payment. On average, each participant earned 59 euros (39 euros at the earliest delay and 20 euros at later time points) and caused donations of 70 euros (40 euros at the earliest delay and 30 euros at later time points). Average earnings and average donations together corresponded to fifteen times the federal hourly minimum wage at the time, or more than 10% of the median monthly household income in our sample.

3.3 Transformations

We ensure comparability of the compensation payments in each lottery and divide them by their expected value. To make intertemporal choices comparable across tasks, we proceed as follows. For choices from the stages UD and MD, we calculate the net present value (expressed in today's numeraire) of a dated future payment of one euro from subjects' smaller-sooner-larger-later choices. Specifically, the net present value is $50/m^*$, where m^* is the subject's switching point.[17] For choices from stage ER, we calculate the (forward) exchange rate $m^*/50$, i.e. the rate of charity-euros per contemporaneous self-euro.

---

[17]The value of the earlier payment (option A) in the multiple price list is always 50 euros. We use the midpoint of the interval where the subjects switched from option A to option B.

4 Reduced-form results

We now document the main qualitative patterns in our data. Our goal is to disentangle the consequence-dated and choice-dated models of prosocial utility by testing the distinctive predictions of the two models. We first outline our estimation strategy and then discuss our results.

4.1 Estimation strategy

We present the average net present values and exchange rates by task. We use non-parametric hypothesis tests (Wilcoxon signed-rank test, paired t test) for inference about differences in means. These tests exploit the within nature of our design and ignore the between-subject variation in choices. The construction of our 95% confidence intervals is based on the procedure developed by Morey (2008) and Cousineau (2005). The procedure is best understood by considering the following auxiliary regression analysis of our results. Let $y_{i,j}$ denote an outcome of interest derived from subject i's selection of task j. We then estimate the saturated regression model separately for the stages UD, MD, and ER:

$$y_{i,j} = \alpha_i + \beta \text{Domain}_j + \sum_\tau \gamma_\tau \text{Delay}_{\tau(j)} + \sum_\tau \delta_\tau \text{Domain}_j \times \text{Delay}_{\tau(j)} + \varepsilon_{i,j}. \quad (5)$$

Here, α_i is a subject fixed effect, Domain_j is a binary variable taking the value of 1 if the earlier dated payment in task j is denoted in charity-euros, $\text{Delay}_{\tau(j)}$ is a binary variable taking the value of 1 if the later dated payment in task j has a delay of τ months, and $\varepsilon_{i,j}$ denotes the individual error term. To account for the nature of the within design, we cluster standard errors at the subject level.

The confidence intervals developed by Morey (2008) and Cousineau (2005) for differences in means across tasks will be similar to the confidence intervals obtained for the corresponding linear combination of regression parameters. We report the estimates of Equation (5) in Table A.2 of the Appendix. Following our experimental design, we start with the analysis of choices under risk and then turn the intertemporal decisions.

4.2 Choice under risk

We can characterize the shape of the flow utility function up to the third derivative from the subjects' choices under risk.

Figure 3 shows the cumulative distribution of the required compensation payments in the risk apportionment tasks. This non-parametric analysis yields two main findings, which we discuss in turn.

Figure 3: This figure plots the cumulative distribution function of the normalized compensation payments m for each of the five stages of the risk apportionment tasks. For each risky choice, we first divide the indifference points by the expected value of the corresponding base lottery without compensation to render choices comparable (see Table 2 for an overview of each stage). For each stage, we then obtain m by taking the average of the three normalized lottery choices. The figure then plots the cumulative distribution function of m for each stage (N = 244). "Risk aversion: Self" and "Risk aversion: Charity" show the distribution of second-order risk attitudes over self-euros and charity-euros. "Prudence: Self" and "Prudence: Charity" show the distribution of third-order risk attributes over self-euros and charity-euros. "Correlation aversion" shows the distribution of the multivariate risk aversion over self-euros and charity-euros.

More than 80% of subjects display second- and third-order risk aversion for self-euros and charity-euros. We can neither reject the null hypothesis that people are on average *equally* risk-averse in both domains (paired Wilcoxon signed-rank test, $p = 0.251$) nor that risk preferences in both domains are

equally distributed (Kolmogorov–Smirnov test, $p = 0.786$). In the following, we will thus assume that the single-attribute utility functions representing utility from self-euros and charity-euros only differ by a multiplicative constant.[18] We also observe a strong positive correlation ($\rho = 0.671$) between subjects' third-order risk aversion (prudence) in the self- and other domain.

Result 1. *Subjects exhibit highly similar attitudes towards risk in payments of self-euros and charity-euros. This observation implies that the corresponding single-attribute utility functions have equal curvature.*

We classify more than 80% of subjects as correlation averse. The risk apportionment tasks deliver a non-parametric measure of the condition for correlation aversion, namely that the cross-derivative with respect to payments in self-euros and charity-euros is negative.

Result 2. *Subjects overwhelmingly display correlation aversion. This implies that the multi-attribute utility function is not additively separable, $u(w, g) \neq f(w) + h(g)$.*

Summing up, we document the non-separability of multi-attribute utility and identical curvatures of the single-attribute utility functions. Both features inform our analysis of intertemporal choices from now on.

4.3   Intertemporal choice

We test our earlier predictions to disentangle consequence-dated and choice-dated prosocial utility. Our earlier finding that the single-attribute utility functions have the same curvature allows us to derive slightly more general conclusions than under the nested case of linear utility.

We start with the univariate discounting tasks (stages *UD-CHARITY* and *UD-SELF*). Here, subjects only face a time trade-off, but no trade-off across domains. Figure 4 shows the net present values of delayed payments of self-euros and charity-euros. We plot the average stated amounts for the subjective evaluation in self-euros m^S for a payment of one self-euro that is delayed

---

[18]The most commonly used one- and two-parameter families of utility functions are pinned down (up to a linear transformation) by their second- and third-order risk aversion.

by an amount of time τ. We report the same result for the subjective evaluation in charity-euros m^C for a donation of one euro that is also delayed by τ.

Figure 4: This figure displays the net present value of a dated payment of one self-euro (blue markers) and the net present value of one charity-euro (red markers) with different delays (N = 244). The net present values are calculated from choices between smaller-sooner and larger-later payments to the subjects or donations. 95% confidence intervals of the mean are calculated according to Morey (2008) and Cousineau (2005).

The net present values are identical between the two domains and decreasing with time. The average stated amounts for m^S and m^C are statistically indistinguishable for all delays τ (paired Wilcoxon signed-rank test, $p > 0.58$ for any τ). This result has two implications related to Prediction 1. First, a decreasing net present value for delayed charity-euro payments is incompatible with the pure choice-dated model. If prosocial utility flows are entirely choice-dated, then delays in implementing the donation payment are simply irrelevant. Our finding is in line with consequence-dated prosocial utility flows. Second, and more compellingly, the discounted utility version of consequence-dated utility can accommodate identical net present values for delayed self-euros and charity-euros and identical curvatures of the single-attribute utility functions (Result 1). This suggests that the same discount factors, $D(\tau)$, are applied to future utility from self-euros and charity-euros. We can rule out the alternative explanation that there are separate discount factors for each domain as, established in Result 1, the univariate utility func-

tions for self-euros and charity-euros have the same curvatures.

Result 3. *In univariate discounting tasks, net present values for delayed self-euro and charity-euro payments are identical and decreasing in the delay. Both patterns are consistent with consequence-dated, but not with choice-dated, prosocial utility.*

We now turn to the choice tasks designed to determine subjective exchange rates between self-euros and charity-euros for different delays (stage *ER*). In these tasks, subjects only face a cross-attribute trade-off, since the time of the payments are the same. Figure 5 shows the average subjective exchange rates F_τ between contemporaneous self-euros and charity-euros.

Figure 5: This figure displays the estimated subjective exchange rates between contemporaneous payments to the subjects and donations, i.e. the number of charity-euros per contemporaneous self-euro. Note that "0 months" indicates payments initiated after three days. 95% confidence intervals of the mean are calculated according to Morey (2008) and Cousineau (2005).

The level of the subjective exchange rate is always above one indicating that subjects on average prefer payments to themselves over equally sized donations (paired t tests at each delay, $p < 0.001$). For the earliest payment date of only three days, subjects exhibit an exchange rate of approximately $F_\tau = 2.07$. One self-euro is valued about twice as much as one charity-euro. More strikingly, we find that the valuation of a self-euro per contemporaneous charity-euro decreases in the delay τ (paired t tests for the change in delay

τ relative to base period, $p_1 = 0.245$, $p_3 = 0.031$, $p_6 = 0.003$, $p_{12} < 0.001$). This means that when the common delay of two payments – one denominated in self-euros and one in charity-euros – increases, our subjects develop a relative preference for charity-euros. Put differently, in these types of choices that only involve the same delay τ in both domains, subjects discount self-euros faster than charity-euros.

A declining forward exchange rate has two implications regarding Prediction 2. First, we cannot rationalize this pattern with the discounted utility version of consequence-dated prosocial utility. If we apply the same discount function to self-euros and charity-euros, the discount factors cancel out as the delays in the two payments are the same. Second, this finding is compatible with choice-dated prosocial utility. If delayed self-euro payments generate delayed utility flows that are discounted, but delayed donations are only associated with choice-dated utility flows, an increase in the common delay affects the discounted utility from self-euros, while leaving the utility derived from donations unaffected. Note that we do not have to invoke the shape of the utility function for this argument: the exchange rate finding is incompatible with discounted utility irrespective of utility curvatures.

Result 4. *Subjective exchange rates between self-euros and charity-euros are declining over time, i.e. a common delay makes self-euros relatively less valuable than charity-euros. This pattern is explained by choice-dated, but not by consequence-dated, prosocial utility.*

Finally, recall that choice tasks on multi-attribute discounting (stages *MD – CHARITY* and *MD – SELF*) combine a cross-attribute trade-off with a time trade-off within a single decision. Our participants had to decide what amount in one domain payable at a later date would make them indifferent to a given amount in the other domain payable at an earlier date. Figure 6 shows the average net present value of one delayed self-euro when expressed in charity-euros today and vice versa.
Figure 6: This figure displays estimated net present values of delayed payments (N = 244). Red markers indicate the net present value of one delayed self-euro expressed in charity-euros today. Blue markers indicate the net present value of one delayed charity-euro expressed in self-euros today. 95% confidence intervals of the mean are calculated according to Morey (2008) and Cousineau (2005).

There are three distinct patterns in our data. First, subjects on average demand less compensation in self-euros at the earlier date for giving up a donation at a later date than vice versa (paired t test for each delay, $p < 0.01$).[19] Intuitively, given that subjects value one self-euro roughly twice as much as a contemporaneous charity-euro, they will require less compensation in their preferred category (self-euros) than in the inferior category (charity-euros). Second, the net present values decrease in the delay of the later payment, implying that payments of both self-euros and charity-euros are valued less as their delay increases (paired t-tests between adjacent delays, $p < 0.01$). Third, we find that the net present value of delayed charity-euros decreases less quickly in the delay τ than the net present value of delayed self-euros (paired t-tests for the difference in rates of change for compensations in self-euros and charity-euros for each time difference, $p < 0.01$).

These non-parametric results relate to Prediction (3) as follows: a decreasing net present value of delayed charity-euros is at odds with pure choice-dated prosocial utility, as the payment date of charity-euros should be in-

---

[19]Specifically, the average WTA for giving up self-euros today for charity-euros tomorrow (WTA_τ^{sc}) is higher than the average WTA for giving up charity-euros today for self-euros tomorrow (WTA_τ^{sc}). In particular, we have $\min_\tau \text{WTA}_\tau^{sc} > \max_\tau \text{WTA}_\tau^{cs}$.

consequential in that case. However, all three patterns are compatible with consequence-dated prosocial utility. A decreasing net present value of more delayed donations naturally follows from stronger discounting. The level differences as well as the difference in slopes are predicted by a lower marginal utility from charity-euros.

Result 5. *In cross-attribute intertemporal decisions, net present values of delayed charity-euro payments are decreasing in their delay, and they are lower and decrease less quickly than required rates of return on delayed self-euros. These patterns are explained by consequence-dated, but not by choice-dated, prosocial utility.*

In summary, our reduced-form analyses provide strong evidence for the existence of *both* choice-dated and consequence-dated components of prosocial utility. We now develop and estimate a structural model that reproduces the documented patterns with a single set of preferences.

5 Structural estimation

Our following structural analysis has two objectives (DellaVigna, 2018). First, we assess the ability of our proposed model of intertemporal prosocial utility to generate the qualitative reduced-form patterns with a quantitatively reasonable parameterization. Second, the estimated model allows us to assess the relative importance of choice-dated and consequence-dated prosocial utility.

We first outline and motivate the functional form of our utility function, provide details about our estimation routine, and discuss the results from a representative agent model before we turn to an individual-level estimation.

5.1 Setup

Building on our conceptual framework and reduced-form results, we posit the following parametric form for our intertemporal utility function:

$$U_t = \underbrace{\alpha \mathbb{1} \left(\sum_{\tau=0}^{\infty} g_{t+\tau} > 0 \right)}_{\text{chioce-dated}} + \underbrace{\sum_{\tau=0}^{\infty} \delta^{\tau} \left(w x_{t+\tau}^{\beta} + (1-w) g_{t+\tau}^{\beta} \right)}_{\text{consequence-dated}}. \qquad (6)$$

The first part represents choice-dated prosocial utility, while the second part captures consequence-dated utility. In this parameterization, α is the choice-dated prosocial utility derived from donating, and δ denotes the one-month utility discount factor. We capture pure altruism by $1 - w$, as it describes the relative value of one charity-euro to a current self-euro. $1 - \beta$ refers to the coefficient of univariate relative risk aversion.

The key elements of our specification follow our reduced-form analysis and the existing literature.[20] First, our earlier findings suggest that we include both choice- and consequence-dated utility. Second, for the flow utility function, we document in our reduced-form analysis that the curvature of the univariate utility from self-euros and the univariate utility from charity-euros have the same curvature and only differ in scale. We, therefore, assume a common parameter, β, to capture the curvature of the utility function when choices involve only one recipient. Third, we also find strong evidence of multivariate risk aversion in our reduced-form analysis, implying a non-additively separable flow utility function in the consequence-dated utility component. Finally, we assume standard exponential discounting as our data only includes payment dates in the future, allowing us to abstract from present bias and to economize on parameters in our baseline specification.

We drop a small number of questions and individuals from our estimation sample. While it is possible to explicitly incorporate a parameter of correlation aversion in the functional form, our primary focus is on intertemporal prosocial utility. Indeed, correlation aversion should only affect 3 out of 36 choices. As such, we abstain from modeling correlation aversion and exclude all choices from stage $X - RA$ in our estimation. In addition, some subjects display a very high degree of risk aversion in the stages $RA - SELF$ and $RA - CHARITY$. As highlighted in Wakker (2008), a CRRA utility function has difficulties matching this behavior, as a constant relative risk aversion greater than one is outside the theoretical range of our structural model. Thus, we exclude 44 subjects with an average normalized switching point greater than 0.9 in the stages $RA - SELF$ and $RA - CHARITY$ to avoid corner solutions.

---

[20]Andreoni and Miller (2002), Andersen et al. (2018), and Fisman et al. (2007) use a similar functional form.

5.2 Estimation

The experiment is carefully designed to provide the required variation to jointly identify the four parameters $\theta = (\alpha, \beta, \delta, w)$ in Equation (6). Univariate risk aversion, $1 - \beta$, is identified from the risky choices in Part B. Conditional on $1 - \beta$, the discount factor δ is separately identified from the univariate discounting stage in Part A of the experiment. The subjective exchange rate from stage ER provides identifying variation for the choice-dated prosocial utility parameter, α. We identify the pure altruism parameter, $1 - w$, from choices involving trade-offs between self-euros and charity-euros such as stage *MD – SELF*, *MD – CHARITY*, and *ER*.

We estimate the structural parameters of our model using a minimum-distance estimator (Newey and McFadden, 1994). Let $m(\theta)$ denote the moments predicted by our structural model, and $\hat{m}$ the vector of observed moments. The minimum-distance estimator selects the parameters $\hat{\theta}$ that minimize the distance the squared distance between the observed and predicted moments. The estimates $\hat{\theta}$ are defined by:

$$\hat{\theta} = \underset{\theta}{\operatorname{argmin}} \quad (m(\theta) - \hat{m})' W (m(\theta) - \hat{m}), \tag{7}$$

where W is a positive definite weighting matrix. We chose a minimum-distance estimator over a maximum likelihood estimator, because it is more robust to outliers that are unlikely according to the model. This challenge is particularly prevalent in the context of charitable giving (DellaVigna, 2018; DellaVigna et al., 2012).

As a vector of moments $\hat{m}$, we use the average normalized switching point in each of our remaining 33 price lists. We normalize individual switching points by applying a linear transformation that maps each price list onto the unit interval such that $\hat{m} \in [0,1]^{33}$. For the choice of the weighting matrix, we follow the suggestion by Altonji and Segal (1996) and use the diagonal of the inverse of the variance-covariance matrix of our empirical moments. We provide additional details about the implementation and reliability of our estimation approach in Appendix B.

5.3 Results

We estimate two models to learn about our parameters of interest. We first estimate a representative agent model that rules out any parameter heterogeneity. Then, we leverage the rich within-subject variation of our data. We estimate the utility function at the subject level and obtain estimated preferences $\hat{\theta}_i$ for each subject (Fisman et al., 2007; Augenblick and Rabin, 2018).

First, we consider the representative agent model. Figure 7 displays the point estimates and the corresponding 95% confidence intervals for the model parameters.
Figure 7: This figures displays the point estimates (black marker) and 95% confidence intervals (gray lines) of the representative agent parameter estimation (N = 200). α is the marginal choice-dated prosocial utility from giving. $1-w$ is the weight on utility from charity-euros in the stationary flow utility function. $1-\beta$ is the coefficient of univariate relative risk aversion. δ is the one-month discount factor.

Our estimated parameter values are all reasonable and, where applicable, in line with the existing literature. For example, we estimate a one-month discount factor of 0.991, which corresponds to a one-year discount factor of 0.906, similar to results observed by Andersen et al. (2018). We estimate a univariate relative risk aversion parameter of 0.808, and we find evidence for a consequence-dated prosocial utility component. Our point estimate of $1-\hat{w} = 0.32$ implies that a donation of 50 euros provides roughly half (i.e. $\frac{1-w}{w}$) of the utility of an identically-dated 50-euro payment to the subject. This magnitude is consistent with our reduced-form estimate of the subjective exchange rate. In addition, there is a choice-dated utility component. We estimate a value of $\hat{\alpha} = 0.62$ that implies that a donation of 50 euros in one month provides about 40% of the utility associated with a 50-euro payment

to the subject with the same delay.

Next, we turn to the individual-level estimation to investigate the role of preference heterogeneity in our sample. We find considerable heterogeneity in preferences. Figure 8 shows the marginal distribution of each preference parameter. The median subject exhibits a consequence-dated prosociality parameter $1 - \hat{w}$ of 0.353, which is in line with the estimate for a representative agent. At the same time, about 20% of respondents have parameter estimates $(1 - \hat{w} = 0)$ that suggest almost no concern for the consequences of their decisions for others. Slightly fewer than 60% of our subjects have parameter estimates $\hat{\alpha} > 0$ that suggest the presence of choice-dated prosociality. Among this group, the degree of choice-dated motivation is widely dispersed with a median parameter estimate of 0.481.

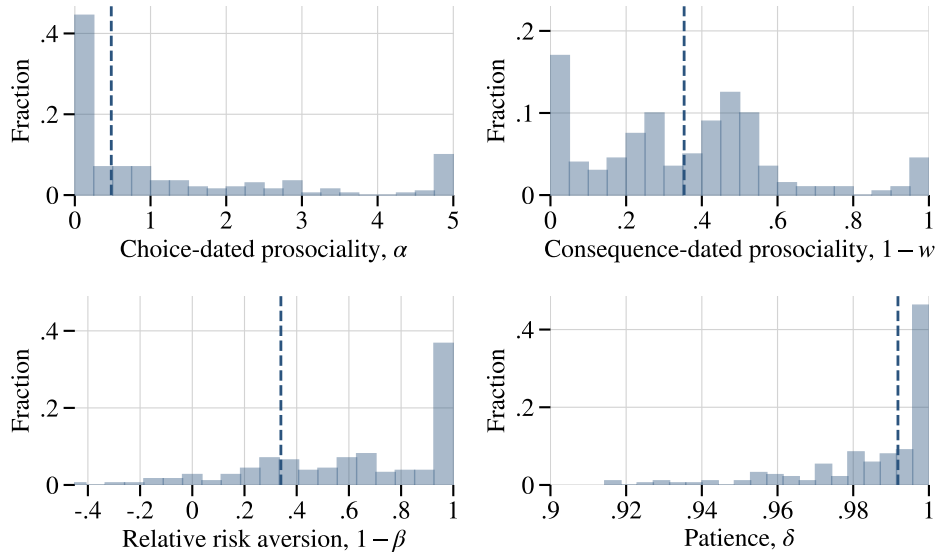

Figure 8: This figure plots the marginal distribution of the model parameters at the subject-level (N = 200). It shows the fraction of the sample that is contained in each bin. The dashed vertical line indicates the median of the distribution. The distribution of $1 - \beta$ excludes fifteen subjects with a coefficient of relative risk aversion smaller than -0.50. The distribution of δ excludes twelve subjects with a one-month discount factor below 0.90.

Looking at the joint distribution between $\hat{\alpha}$ and $(1 - \hat{w})$ we find a negative correlation of $\rho = -0.417$. This strong correlation suggests that the prosocial motivations underlying these differently-dated utility flows are substitutes rather than complements at the individual level. Put differently, choice-dated and consequence-dated motivations characterize different types of people.

Our data are compatible with the interpretation that, while some people donate out of pure altruism, others are driven by the feeling of warm glow.

The declining subjective exchange rate between self-euro and charity-euro payments with the same delay is one of the core findings from our reduced form analysis (see Appendix Figure A.3). Our estimated model replicates this pattern, and we discuss the implications for the median of the individual-specific parameters. First, consider two payments executed in a month from today. A 50-euro payment to the subject in one month provides 2.42 utils of discounted utility to a subject, whereas a 50-euro donation in one month provides 1.32 utils from consequence-dated utility flows and 0.48 utils from the choice-dated utility flow. Second, consider two payments executed in a year from today. A 50-euro payment to the subject in a year provides 2.21 discounted utils to a subject, whereas a 50-euro donation in a year provides only 1.21 utils from consequence-dated utility flows and still 0.48 utils from the choice-dated utility flow. Going from a delay of only a month to a full year leads to an increase in the relative weight of the choice-dated utility prosocial utility from 26.7% to 28.5% in this example. As a consequence, the forward exchange rate decreases by 0.28 euros when payments are executed in a year from today rather than a month. This change is remarkably close to our observed decrease of 0.20 euros in our experiment.

6   Conclusion

We study the intertemporal dimension of prosocial behavior and propose a distinction between choice-dated and consequence-dated flows of prosocial utility. This conceptual approach generalizes differences between psychological motivations explored in the existing literature and delivers testable implications for intertemporal prosocial behavior. Empirically, we conduct a high-stakes donation experiment that provides a comprehensive characterization of the intertemporal multi-attribute utility function using reduced-form and structural approaches. We find that the majority of individuals exhibit both choice-dated and consequence-dated prosocial utility. Furthermore, both motives are quantitatively meaningful, and there is a strong negative correlation between their importance as individuals are either primarily motivated by choice-dated or consequence-dated considerations.

We conclude with three comments on the limitations and potential promise of the approach taken in this paper. First, the proposed conceptual distinction between consequence-dated and choice-dated utility is deliberately chosen to bridge theoretical work on intertemporal choice with largely empirical work on specific prosocial motivations such as warm glow and pure altruism. At the same time, this taxonomy remains a reduced-form perspective on the psychological mechanisms underlying prosocial behavior. It is thus complementary to work that sheds light on the sources of pure time preferences about the outcomes of others. For example, our approach and findings provide a motivation to further examine *why* people prefer helping others sooner rather than later. Second, we abstract from the implications of our approach for time-inconsistent behavior. This topic has received significant attention following work on present-biased preferences and is the focus of related work. Third, while the present paper introduces a toolkit for analyzing the time structure of prosocial utility flows and hints at the usefulness of this approach for understanding prosocial decision-making, it does so in a specific high-stakes donation context using a specific experimental paradigm that relies on the well-studied multiple price list methodology and monetary payments. One avenue for future work is to examine the implications of whether and how intertemporal prosocial motivations interact with these design choices.

A Tables and Figures

Table A.1: Summary statistics

	Observations	Mean	Std. dev.	Min	25th	Median	75th	Max
Age	244	25	5.5	18	22	23	26	61
Female	244	.57	.5	0	0	1	1	1
Household income	244	1,446	1,133	0	650	1,000	2,000	4,000
Savings	244	.54	.5	0	0	1	1	1
Education (years)	244	16	3.5	3	15	16	18	29
Student	244	.91	.29	0	1	1	1	1
Political orientation	244	2.3	1.3	0	1	2	3	6
Siblings	244	1.5	1.2	0	1	1	2	7
Raven score	244	6.1	1.7	0	5	6	7	10

Note: This table shows summary statistics for the full sample. "Household income" is the self-reported total monthly household income after taxes and transfers (in euros). "Savings" is a binary variable taking the value of 1 if the subject reported that she is able to save money each month. "Education (years)" are the subject's total years of education starting from primary school. "Student" is a binary variable taking value of 1 if the subject is enrolled at a university degree program. "Political orientation" is measured on a scale from 1 ("rather left") to 7 ("rather right"). "Siblings" are the total number of siblings. "Raven score" is the number of correctly solved Raven matrices out of ten.

Table A.2: Regression analysis of intertemporal choices

	Univariate discounting			Multivariate discounting			Exchange rate
	(1)	(2)	(3)	(4)	(5)	(6)	(7)
charity-euro	-0.005		0.001	2.277		2.897

			(0.013)			(0.471)	
Constant	0.843	0.944	0.943	1.430	3.381	1.933	2.070
	(0.004)	(0.004)	(0.005)	(0.268)	(0.140)	(0.308)	(0.030)
N	1952	1952	1952	1952	1952	1952	1220
R^2	0.386	0.620	0.621	0.428	0.404	0.437	0.921
Subject FE	Yes	Yes	Yes	Yes	Yes	Yes	Yes

Note: This table shows pooled OLS regression estimates where the unit of observation are subject-choices. In columns 1–3, we include all choices from the two univariate discounting stages (UD-S, UD-C). The dependent variable is the net present value $y_{i,\tau,d}$ of the delayed payment, where i denotes the subject, τ the delay in months, and d is the numéraire of the payments (self-euros or charity-euros). Columns 4–6 include all choices from the two multivariate discounting stages (MD-S, MD-C). The dependent variable is the net present value $y_{i,\tau,d}$ of the delayed payment using the type d of the earlier payment (self-euros or charity-euros) as numéraire. In column 7, we include all choices from the exchange rate stage ER. The dependent variable is the implied (forward) exchange rate $y_{i,\tau}$ at different delays τ. "Charity-euro" is a binary indicator variable taking the value of 1 if the numéraire of the earlier payment are charity-euros. "τ month(s)" is a binary indicator variable taking the value of 1 if the later payment is received with a delay of τ month(s), where $\tau = 1$ month is the omitted category in columns 1–6 and "0 months" is the omitted category in column 7. All regressions include subject fixed effects for the 244 subjects. Standard errors are clustered at the subject level and shown in parentheses.

Figure A.1: This is an example of the decision screen as seen by subjects in stage *MD – SELF* of the intertemporal choice part of the experiment. The original instructions in German are shown. In each row, subjects indicate whether they prefer option A or option B by selecting the appropriate circle in each row. Option A on the left-hand side offers 50 self-euros today. Option B on the right-hand side offers increasing amounts of charity-euros from zero to 262.50 euros. The amount will be wired to *Operation ASHA* in six months. All price lists in the intertemporal choice part of our experiment are presented in this format. We vary only (i) the amount offered in option B, (ii) the timing of payments (both for option A and option B), and (iii) whether payments are denoted in self-euros or charity-euros. The decision screens are otherwise identical.

Entscheidung

Ihre **Ausgangsausstattung** für die folgende Entscheidung:

- **40,00 €** als **Auszahlung an Sie**, und
- **0,00 €** als **Spendenauszahlung** an die Organisation *Operation ASHA*.

Zusätzlich müssen Sie sich nun zwischen **Lotterie A** und **Lotterie B** entscheiden.

Lotterie A	Lotterie B

Lotterie A

Wenn **Kopf** *geworfen wird:* 10,00 € **weniger** Auszahlung an Sie

Wenn **Zahl** *geworfen wird:* Zusatzlotterie für **Ihre** Auszahlung — Mit 20% Wahrscheinlichkeit: **Gewinn** von 28€ **für Sie**; Mit 80% Wahrscheinlichkeit: **Verlust** von 7€ **für Sie** — 80% ... 20% ... -7 € 0 € 28 €

Lotterie B

Wenn **Kopf** *geworfen wird:* 10,00 € **weniger** Auszahlung an Sie UND Zusatzlotterie für **Ihre** Auszahlung — Mit 20% Wahrscheinlichkeit: **Gewinn** von 28€ **für Sie**; Mit 80% Wahrscheinlichkeit: **Verlust** von 7€ **für Sie** — 80% ... 20% ... -7 € 0 € 28 € UND **X €** zusätzliche Auszahlung an Sie

Wenn **Zahl** *geworfen wird:* **X €** zusätzliche Auszahlung an Sie

Hinweis: **X €** wird also immer dann gezahlt, wenn Sie **Lotterie B** wählen, und zwar unabhängig davon, ob *Kopf* oder *Zahl* geworfen wird.
Ob **X** positiv (ein Gewinn) oder negativ (ein Verlust) ist, hängt von der Entscheidungssituation ab.

Lotterie A	○ ○	Lotterie B mit **X = -5,00 €**
Lotterie A	○ ○	Lotterie B mit **X = -4,50 €**
Lotterie A	○ ○	Lotterie B mit **X = -4,00 €**
Lotterie A	○ ○	Lotterie B mit **X = -3,50 €**
Lotterie A	○ ○	Lotterie B mit **X = -3,00 €**
Lotterie A	○ ○	Lotterie B mit **X = -2,50 €**
Lotterie A	○ ○	Lotterie B mit **X = -2,00 €**
Lotterie A	○ ○	Lotterie B mit **X = -1,50 €**
Lotterie A	○ ○	Lotterie B mit **X = -1,00 €**
Lotterie A	○ ○	Lotterie B mit **X = -0,50 €**
Lotterie A	○ ○	Lotterie B mit **X = 0,00 €**
Lotterie A	○ ○	Lotterie B mit **X = 0,50 €**
Lotterie A	○ ○	Lotterie B mit **X = 1,00 €**
Lotterie A	○ ○	Lotterie B mit **X = 1,50 €**
Lotterie A	○ ○	Lotterie B mit **X = 2,00 €**
Lotterie A	○ ○	Lotterie B mit **X = 2,50 €**
Lotterie A	○ ○	Lotterie B mit **X = 3,00 €**
Lotterie A	○ ○	Lotterie B mit **X = 3,50 €**
Lotterie A	○ ○	Lotterie B mit **X = 4,00 €**
Lotterie A	○ ○	Lotterie B mit **X = 4,50 €**
Lotterie A	○ ○	Lotterie B mit **X = 5,00 €**

Weiter

Figure A.2: This is an example of the decision screen as seen by subjects in stage *RA – SELF* of the risky choice part of the experiment. The original instructions in German are shown. At the top of the screen, subjects are informed about their initial endowment **e** of 40 self-euros and zero charity-euros. Next, subjects see two boxes that contain a visual representation of lottery A and lottery B. In each box, the upper part explains the consequences when the simulated coin toss yields head, whereas the lower part explains the consequences if it yields tails. In the lower part of the screen, subjects indicate whether they prefer lottery A or lottery B by selecting the appropriate circle in each row. The right-hand side shows the compensation amounts **m** that are to be added to lottery B. They range from -5.00 self-euros to 5.00 self-euros. All decisions in the risky choice part of our experiment are presented in this format. We vary only (i) the lotteries and (ii) the range of the compensation amounts. The decision screens are otherwise identical.
Figure A.3: This figure plots the empirical and the estimated moments for our estimation sample (N = 200). The moments are the average switching point in each of our 33 price lists. The upper panel shows moments for intertemporal choices, while the lower panel reports moments for risky choices from part B of the experiment. For intertemporal choices, labels on the vertical axis groups task by their stage (UD-S, UD-C, FX, MD-S, MD-C) and indicate the delay of the sooner and the later payment. For example, "6-6" means that both payments were made 6 months after the experiment. For risky choices, we indicate the size of the deduction R_2 (see Table 2 for more details).
Figure A.4: This figure shows the joint distribution (N = 200) of the choice-dated prosociality parameter, α, and the consequence-dated prosociality parameter, $1 - w$. The circles in dark gray indicate the subsample of subjects with a degree of risk aversion that is outside the range of the structural model, i.e. they have a coefficient of relative risk aversion greater than 0.90. The Spearman correlation is -0.417 in the full sample and -0.447 in the subsample.

B Structural estimation

Practical estimation   To calculate the minimum-distance estimator $\hat{\theta}$, we employ the L-BFGS-B algorithm, which is appropriate for constrained optimization (Byrd et al., 1995).[1] We impose the following box constraints: $\delta \in (0, 1]$ (positive discounting), $\beta \in [0, 5]$, $\alpha \in [0, 5]$ (non-negative choice-dated utility) and $w \in [0, 1]$ (altruism weight between 0 and 1). As local minima are a natural concern in any structural estimation, we repeatedly estimate our model using ten randomly-chosen initial values from a uniform distribution over the parameter space. Moreover, we always include as initial values at least one parameter draw where $\alpha = 1 - w = 0$ to ensure that purely selfish preferences were in the consideration set of the estimator. As our final parameter estimate, $\hat{\theta}$, we choose the estimate with the minimum weighted distance among all ten estimates. We obtain standard errors from an estimator of the asymptotic variance-covariance matrix of the estimator:

$$(\hat{G}'W\hat{G})^{-1}(\hat{G}'W\hat{\Lambda}W\hat{G})(\hat{G}'W\hat{G})^{-1}, \tag{8}$$

where $\hat{G} = N^{-1}\sum_{i=1}^{N} \nabla_\theta m_i(\hat{\theta})$ and $\hat{\Lambda} = Var[m(\hat{\theta})]$. We also show the empirical and estimated moments in Figure A.3.

Monte Carlo   We also conducted Monte Carlo experiments to increase our confidence in the estimation procedure. We simulate the choices of $N = 200$ agents with preferences θ_0 for randomly-chosen values of θ_0. For each θ_0, we start our estimation procedure at a perturbed initial value of $\theta_0 + \xi$. The minimum-distance estimator is able to back out θ_0 in our simulation experiments.

---

[1] We use a Python implementation of this estimation routine (Gabler, 2020).

C Conceptual framework

We briefly discuss choice-dated prosocial utility and conditions that imply a declining forward exchange rate. Recall that t denotes the current period, τ indexes time relative to t, $x_{t+\tau}$ denotes a dated payment to the decision-maker to be received at $t + \tau$, and $g_{t+\tau}$ represents a donation to charity that was caused at time t and will be received by the charity in τ periods. Suppose that the decision-maker's preferences are given by

$$U_t = \alpha(\mathbf{g}) + \sum_{\tau=0}^{\infty} D(\tau) u(x_{t+\tau}), \tag{9}$$

where $\alpha(\cdot)$ captures the choice-dated prosocial utility derived from the stream of future donations $\mathbf{g} = (g_{t+\tau})_\tau$ that has been *caused* in t. As we are mainly interested in the effect of delays, we replace α by a linear approximation

$$\alpha(\mathbf{g}) \approx a \sum_{\tau=0}^{\infty} D^c(\tau) g_{t+\tau}, \tag{10}$$

where $D^c(\tau)$ can be interpreted as an implicit "discount factor" that describes how choice-dated prosocial utility from causing a future charitable donation depreciates with the delay of the donation. We provide a sufficient condition for an asymptotically declining forward exchange rate:

Assumption 1. *The implicit discount factor $D^c(\tau)$ declines at a lower rate than the subjective discount factor $D(\tau)$, i.e. $\lim_{\tau \to \infty} D^c(\tau)/D(\tau) = \infty$.*

Intuitively, this implies that the choice-dated prosocial utility from the act of giving is less sensitive to the delay τ than the utility from payments to the self.[2] Thus, for large τ, the choice-dated prosocial utility will be insensitive to the delay τ *relative* to the sensitivity of utility from self-euros: the forward exchange rate will converge to zero.

We provide a simple example to illustrate why we would expect this condition to hold. Suppose that causing a delayed donation $g_{t+\tau}$ at time t provides an immediate feeling of warm glow (Andreoni, 1989), $\bar{\alpha}$, independent of the size of the donation itself, in addition to other sources of choice-dated prosocial

---

[2]If we are willing to assume exponential discounting, i.e. $D^c(\tau) = \delta_c^\tau$ and $D(\tau) = \delta^\tau$, the assumption is equivalent to $\delta_c > \delta$.

utility, i.e. suppose that the choice-dated prosocial utility generated by $g_{t+\tau}$ is:

$$\bar{\alpha}\mathbb{1}\,(g_{t+\tau} > 0) + v_{\tau}(g_{t+\tau}), \tag{11}$$

where $v_{\tau}(g_{t+\tau})$ is a family of positive function. Today, the decision-maker prefers a delayed donation $g_{t+\tau}$ in τ periods to an equally delayed amount $x_{t+\tau}$ of self-euros if

$$\bar{\alpha} + v_{\tau}(g_{t+\tau}) \geq D(\tau)u(x) \iff \underbrace{\frac{\bar{\alpha}}{D(\tau)u(x)}}_{\rightarrow \infty} + \underbrace{\frac{v_{\tau}(g_{t+\tau})}{D(\tau)u(x)}}_{\geq 0} \geq 1. \tag{12}$$

Thus, for large τ, the decision-maker will prefer the donation to contemporaneous self-euros, implying an asymptotically declining forward exchange rate. Note that we only need the existence of an (arbitrarily small) positive lower bound on the utility from the act of giving itself to obtain this result:

Proposition 1. *Suppose that the choice-dated prosocial utility from causing a dated donation g at time t that will be received by the charity at $t + \tau$ is bounded from below by $\bar{\alpha} > 0$. Then, the forward exchange rate converges to zero.*

Intuitively, the subjective discount factors imply that the present value of future self-euros becomes negligible for large τ and eventually falls below the lower bound on the immediate choice-dated prosocial utility (e.g. "warm glow"). In particular, we do not need any additional assumptions on the source of prosocial utilities.

D   Experimental Instructions

The original instructions used in the laboratory experiment are in German. We provide an English translation of the instructions below. The experiment has two parts. Each part consists of five different stages and each stage contains multiple price lists. To avoid repetitions, we only include the translation of one price list per stage. Within a stage, the instructions are constant across price lists except for changes in the monetary amounts or the number of months until a payment is made. See Section 3 of the paper for more details on how the price lists were constructed. The following sections contain the translations:

D.1   Introduction

Welcome and thank you for your interest in this study!

For your participation you will receive a fixed payment of 10.00 €, which will be paid to you by bank transfer after the study. In this study you will make decisions on the computer. Depending on how you decide you can earn additional money.

You are not allowed to talk to other participants during the study. Please turn off your mobile phone now, so that other participants will not be disturbed. Please only use the designated functions on the computer and make your entries using the keyboard and the mouse. If you have any questions, please raise your hand. Your question will be answered at your seat.

On the following screens you will see detailed information concerning the study. After reading this information you can confirm or refuse your participation.

To proceed click "Next".

Information on participating in this study by the *BonnEcon-Lab*

The following information has been sent to you via email along with the con-

firmation of your registration for this study. You will receive this information again now. Once you have read the subsequent declaration of consent you can confirm your participation by clicking on "I agree".

[followed by mandated exclusion restrictions for participation in this study]

[**end of screen**]

Information

In the follow part of this study, you will see important information, concerning tuberculosis and its possible treatment, that is relevant for your subsequent decisions. Please read all information carefully.

[**end of screen**]

Information about Tuberculosis

What is tuberculosis?

Tuberculosis – also called consumptiveness or White Death – is an infectious disease, which is caused by bacteria. Roughly one third of all humans are infected with the pathogen of tuberculosis. Active tuberculosis breaks out among 5 to 10% of all those infected. Tuberculosis is primarily airborne. This is also why a quick treatment is necessary.

What are the symptoms of tuberculosis?

Tuberculosis patients often suffer from generalized symptoms like fatigue, feeling of weakness, lack of appetite, and weight loss. At an advanced stage of lung tuberculosis, the patient coughs up blood, leading to the so-called rush of blood. Without treatment a person with tuberculosis dies with a probability of 43%.

How prevalent is tuberculosis?

In the year 2014, 6 million people have been recorded as falling ill with active tuberculosis. Almost 1.5 million people die of tuberculosis each year. This means more deaths are caused by tuberculosis than HIV, malaria, or any other infectious disease.

Is tuberculosis curable?

Today tuberculosis is curable. Treatment is administered by giving antibiotics several times each week over a period of 6 months. It is important that there is no interruption of treatment. In the years from 2000 to 2014 approximately 43 million human lives were saved due to the effective diagnosis and treatment of tuberculosis. The success rate of treatment for a new infection is often above 85%. The preceding numbers and information are provided by the

Figure D.1: Typical appearance of a tuberculosis patient

World Health Organization (WHO), the United Nations' institution for the international public health, and are freely available. You can check this information on the web page of the WHO after this study.

[**end of screen**]

[**end of screen**]

Your decision

In the course of this study you can choose between options that have different consequences. In particular, you can choose between options with the following consequences:

Additional Payment: If you choose this option, you will receive an additional payment.

Saving a Human Life: If you choose this option, you will not receive an additional payment. This option has another consequence: You save one human life.

After it has emerged which option will be implemented for you, it will be carried out exactly as described. On the next tab you will receive more information about the implementation of Saving a Human Life.

[**end of screen**]

Information about saving a human life

How will a human life be saved?

Depending on how you decide, a human life can be saved. A human life will be saved by arranging a donation of 350.00 € on your behalf to an organization that identifies and treats people suffering from tuberculosis. This donation will be executed for you by the BonnEconLab after the study. The entire donation amount will be used by the organization for the direct treatment of tuberculosis.

What does it mean to "save a life"?

In this context, to save a human life means to successfully cure one person of tuberculosis, who *otherwise* would have died from the disease. This means in particular: The donation amount is sufficient to identify and cure as many sick people such that there is at least one person among them, who would otherwise have died from tuberculosis in expectation. The calculation of the amount accommodates the fact that there are other ways (e.g., the national health care system) through which people can be cured. That means: **The amount of 350.00 € was calculated in such a way that the organization can save at least one additional human from death.**

On the next tab you will receive additional information about the possible saving of a human life and details about the organization that treats tuberculosis patients.

[**end of screen**]

Operation ASHA

Your decisions can save a human life. Depending on how you decide, an amount of 350.00 € will be transferred to the organization *Operation ASHA* after the study.

Operation ASHA is a charity organization that has specialized in the treatment of tuberculosis in disadvantaged communities since 2005. The work of *Operation ASHA* is based on the insight that the biggest obstacle for the treatment of tuberculosis is the interruption of the necessary 6-month-long regular intake of medication. For a successful treatment the patient has to come to a medical facility twice a week – more than 60 times in total – to take the medication. An interruption or termination of the treatment is fatal, because this strongly enhances the development of a drug-resistant form of tuberculosis. This form of tuberculosis is much more difficult to treat and almost always leads to death.

To overcome this problem, *Operation ASHA* developed a concept that guarantees the regular treatment through immediate spatial proximity to the patient. A possible non-adherence is additionally prevented by visiting the patient at home. By now *Operation ASHA* runs more than 360 treatment centers, almost all of which are located in the poorest regions of India. More than 60,000 sick individuals have been identified and treated this way.

Figure D.2: An employee of Operation ASHA provides medicine to a tuberculosis patient.

Operation ASHA is an internationally recognized organization, and its success has been covered by many news outlets including the New York Times, the BBC, and Deutsche Welle. MIT and University College London have already conducted research projects about the fight against tuberculosis in cooperation with *Operation ASHA*. The treatment method employed by *Operation ASHA* is described by the World Health Organization (WHO) as "highly efficient and cost-effective".

[**end of screen**]

What determines the donation amount for saving a human life?

The donation amount ensures that at least one human life is saved in expectation.

The information used for the calculation of the donation amount exclusively consists of public statements by the World Health Organization (WHO), peer-reviewed research studies, statistical releases from the Indian government, and published figures from *Operation ASHA*. In the calculation all information was interpreted in a conservative way and more pessimistic estimates were used in case of doubt such that the donation amount of 350.00 € is, if anything, higher than the actual costs associated with saving a human life. Moreover, the calculation was based on the treatment success rate of *Operation ASHA* and the mortality rate of an alternative treatment by the national tuberculosis program in India. Furthermore, different detection rates for new cases of tuberculosis have been accounted for.

Based on a very high number of cases, one can illustrate the contribution of your donation as follows:

With your donation, *Operation ASHA* can treat five additional tuberculosis patients.

If these five sick individuals were not treated by *Operation ASHA*, one patient would die in expectation. If five people are treated by means of your donation, no patient dies in expectation. Based on these expected values, one human life will be saved with your donation. This relationship is depicted in the following diagram.

a) Without treatment by *Operation ASHA*, one of five individuals sick with tuberculosis will die in expectation.

b) With the donation five individuals sick with tuberculosis can be treated by *Operation ASHA*, and none of these individuals will die in expectation.

An agreement with *Operation ASHA* for the purpose of this study ensures

that 100% of the donation amount will exclusively be used for the diagnosis and treatment of tuberculosis patients. That means that every euro of the donation amount will directly go toward saving human lives.

[**end of screen**]

Summary

Tuberculosis

The success rate of medical treatment for a new infection is very high. Nevertheless, 1.5 million people die from tuberculosis each year. The biggest obstacle for the cure of tuberculosis is a possible termination of the regular treatment with antibiotics. The concept of *Operation ASHA* is therefore based on having direct spatial proximity to its patients and being able to control and account for the regular intake of medication.

Your decision

In the course of this study you can choose between options that have different consequences. In particular, you can choose between options with the following consequences: You can choose the additional monetary payment. If you choose the other option, you will not receive an additional monetary payment, but you can save a human life. Concretely, by choosing the other option you will cause a donation. The donation of 350.00 € will be paid on your behalf, which is sufficient not only to cure one person, but to actually save that person from dying of tuberculosis.

How is the human life saved?

The donation amount of 350.00 € already accounts for the fact that a sick person could also have survived without treatment by *Operation ASHA*; or that he could instead have been treated by the national health care system. This is why the amount is sufficient for the diagnosis and complete treatment of several affected individuals.

Please note: **This is not a hypothetical game**. The option to be implemented for you will actually be carried out – exactly as described – by the *BonnEcon-Lab*. You will receive the money in case you choose the additional monetary payment. In case you choose to save a human life, we will allow inspection of the confirmed bank transfer to the organization *Operation ASHA* upon request.

If you have individual questions, you can also direct these by email after the study to nachbesprechung@uni-bonn.de. You find this email address on the back of your seating card. You can take it home with you. Click on "Next", if

you have carefully read the information on this page. Please note: You can only click on the button "Next" once you have spent at least five minutes on the seven tabs of this page.

[**end of screen**]

Information on the next part of this study

In the next part of this study, we will ask you to make a series of decisions in which you can choose between two monetary payments. The dates on which the two monetary payments are made can differ.

About this part of the study

This part of the study consists of five parts. In each part, you will make a decision in five different decision-making scenarios. At the beginning of each part, you will receive information that is relevant for this part. At the beginning of each decision-making scenario, you will also receive additional information for this particular decision-making scenario.

Payments in this part of the study

All monetary payments in this part of the study will be made by bank transfer. Each bank transfer will be made on the exact date that was indicated for the monetary payments. If, for example, a decision is about a monetary payment today, the corresponding monetary amount will be sent to you by a bank transfer today. If the decision involves a monetary payment in one month, a bank transfer with the corresponding amount will be made exactly one month from now.

In what follows, you will face a series of decision-making scenarios. One of these decision-making scenarios will be randomly selected by the computer at the end of this study. Your decision in *this* decision-making scenario will be implemented at the end of this study.

Remember:

- Every decision-making scenario can be relevant for your monetary payment.

- Your decisions in this part determine both **to whom** the monetary payment will go and **at which date** the monetary payment will be made.

- All monetary payments will be made by bank transfer.

[**end of screen**]

What does it mean that a donation will be made earlier or later?

If a donation is made earlier because of your decisions, help will be available earlier and hence people can be saved from death at an earlier point in time.

If a donation is made later, for example, in one year from now, then help will only be available later. Hence, people can only be saved from death at a later point in time. This means that the donation will be too late to help some patients that have tuberculosis in the present. In this case, patients who got sick at a later date will receive treatment instead.

The **size of the donation** is important, because more people can be helped with more money.

When making the following decisions, you should therefore take into account **when** the donation will be made and **how much** will be donated based on your decisions.

[**end of screen**]

D.2 Experiment Part A

D.2.1 UD-S

Information for the current part

In the following, you will see a series of decision-making scenarios in which you can choose between Option A and Option B.

- **Option A**: A **smaller** monetary payment **to you** at an **earlier** date.

- **Option B**: A **larger** monetary payment **to you** at a **later** date.

Thus, you can make a decision about a payment to yourself. You have the choice between a monetary payment that is smaller and made earlier; and a monetary payment that is larger, but made later.

Please note:

- Each of the following decisions could be the one that is actually implemented.

- **All** monetary payments will be made by **bank transfer**.

[**end of screen**]

Information for the decision-making scenario on the next page

[Box that repeats the relevant information for the current part of the study]

On the next page, you will see a list of choices between

- **Option A**: A smaller monetary payment to you today.

- **Option B**: A larger monetary payment to you in 12 months.

You can thus decide whether you are willing to wait to receive a larger monetary payment.

[**end of screen**]

You can now make your decision

Please indicate in each row of this table whether you choose **Option A** or **Option B**.

	Option A	Option B
50.00 € for you today ∘	∘ 50.00 € for you in 12 months
50.00 € for you today ∘	∘ 52.50 € for you in 12 months
50.00 € for you today ∘	∘ 55.00 € for you in 12 months
. . . ∘	∘ . . .
50.00 € for you today ∘	∘ 120.00 € for you in 12 months
50.00 € for you today ∘	∘ 122.50 € for you in 12 months
50.00 € for you today ∘	∘ 125.00 € for you in 12 months

Automatic completion: We have activated a fill-in aid that automatically fills out the remaining rows so you don't have to click as much.

[**end of screen**]

D.2.2 UD-C

Information for the current part

In the following, you will see a series of decision-making scenarios in which you can choose between Option A and Option B.

- **Option A**: A **smaller** monetary payment **to *Operation ASHA*** at an **earlier** date.

  You are making a smaller contribution to saving lives and the contribution is made earlier.

- **Option B**: A **larger** monetary payment **to *Operation ASHA*** at a **later** date.

  You are making a larger contribution to saving lives. However, the contribution is made later, so there is a delay.

Thus, you can choose whether you want to make a smaller donation at an earlier date to save fewer human lives, or whether you want to wait to make a larger donation at a later date to save more human lives.

Please note:

- Each of the following decisions could be the one that is actually implemented.

- **All** monetary payments will be made by **bank transfer**.

[**end of screen**]

Information for the decision-making scenario on the next page

[Box that repeats the relevant information for the current part of the study]

On the next page, you will see a list of choices between

- **Option A**: A smaller monetary payment to *Operation ASHA* today.

- **Option B**: A larger monetary payment to *Operation ASHA* in 12 months.

26

100% of the donation amount will be used to save human lives.

You can thus decide whether you prefer to save fewer human lives at an earlier date in the immediate future, or whether you want to help save more human lives in the future, but with a greater delay.

[**end of screen**]

You can now make your decision

Please indicate in each row of this table whether you choose **Option A** or **Option B**.

Option A	Option B
50.00 € for Operation ASHA today ○	○ 50.00 € for Operation ASHA in 12 months
50.00 € for Operation ASHA today ○	○ 52.50 € for Operation ASHA in 12 months
50.00 € for Operation ASHA today ○	○ 55.00 € for Operation ASHA in 12 months
… ○	○ …
50.00 € for Operation ASHA today ○	○ 120.00 € for Operation ASHA in 12 months
50.00 € for Operation ASHA today ○	○ 122.50 € for Operation ASHA in 12 months
50.00 € for Operation ASHA today ○	○ 125.00 € for Operation ASHA in 12 months

Automatic completion: We have activated a fill-in aid that automatically fills out the remaining rows so you don't have to click as much.

[**end of screen**]

D.2.3 ER

Information for the current part

In the following, you will see a series of decision-making scenarios in which you can choose between Option A and Option B.

- **Option A**: Monetary payment **to you** at a **given** date.

- **Option B**: Monetary payment **to Operation ASHA** on the **same** date.

  You are making a contribution to saving human lives on the same date that you would have received your monetary payment if you had chosen **Option A**.

Thus, you can choose whether you prefer making a monetary payment to yourself on a given date, or whether you prefer making a donation to help save human lives on the same date.

Please note:

- Each of the following decisions could be the one that is actually implemented.

- **All** monetary payments will be made by **bank transfer**.

[**end of screen**]

Information for the decision-making scenario on the next page

[Box that repeats the relevant information for the current part of the study]

On the next page, you will see a list of choices between

- **Option A**: A monetary payment to *you* in 12 months.

- **Option B**: A monetary payment to *Operation ASHA* in 12 months.

100% of the donation amount will be used to save human lives.

You can thus decide whether you are willing to forego a monetary payment to yourself in 12 months in order to save human lives.

[**end of screen**]

You can now make your decision

Please indicate in each row of this table whether you choose **Option A** or **Option B**.

Option A	Option B
50.00 € for you in 12 months ∘	∘ 0.00 € for Operation ASHA in 12 months
50.00 € for you in 12 months ∘	∘ 10.00 € for Operation ASHA in 12 months
50.00 € for you in 12 months ∘	∘ 20.00 € for Operation ASHA in 12 months
. . . ∘	∘ . . .
50.00 € for you in 12 months ∘	∘ 180.00 € for Operation ASHA in 12 months
50.00 € for you in 12 months ∘	∘ 190.00 € for Operation ASHA in 12 months
50.00 € for you in 12 months ∘	∘ 200.00 € for Operation ASHA in 12 months

[**end of screen**]

D.2.4 MD-S

Information for the current part

In the following, you will see a series of decision-making scenarios in which you can choose between Option A and Option B.

- **Option A**: A monetary payment **to you** at an **earlier** date.

- **Option B**: A monetary payment **to Operation ASHA** at a **later** date.

  You are making a contribution to saving lives. However, the contribution is made later, so there is a delay.

Thus, you can choose whether you prefer a monetary payment to yourself at an earlier date, or whether you prefer to wait to make a larger donation to help save human lives at a later date.

Please note:

- Each of the following decisions could be the one that is actually implemented.

- **All** monetary payments will be made by **bank transfer**.

[**end of screen**]

Information for the decision-making scenario on the next page

[Box that repeats the relevant information for the current part of the study]

On the next page, you will see a list of choices between

- **Option A**: A monetary payment to *you* today.

- **Option B**: A monetary payment to *Operation ASHA* in 12 months.

100% of the donation amount will be used to save human lives.

You can thus decide whether you are willing to forego a monetary payment to yourself at an earlier date to save human lives at a later date.

[**end of screen**]

You can now make your decision

Please indicate in each row of this table whether you choose **Option A** or **Option B**.

Option A	Option B
50.00 € for you today ∘	∘ 0.00 € for Operation ASHA in 12 months
50.00 € for you today ∘	∘ 15.00 € for Operation ASHA in 12 months
50.00 € for you today ∘	∘ 30.00 € for Operation ASHA in 12 months
. . . ∘	∘ . . .
50.00 € for you today ∘	∘ 345.00 € for Operation ASHA in 12 months
50.00 € for you today ∘	∘ 360.00 € for Operation ASHA in 12 months
50.00 € for you today ∘	∘ 375.00 € for Operation ASHA in 12 months

Automatic completion: We have activated a fill-in aid that automatically fills out the remaining rows so you don't have to click as much.

D.3 Experiment Part B

Task description

In the following part of the study, we ask you make a series of decisions involving a choice between two lotteries, **Lottery A** and **Lottery B**. Both lotteries will be determined by a fair coin toss. That means that there is a 50% chance that it lands on heads, and a 50% chance that it lands on tails.

Before each lottery choice, you will receive information about the initial endowment in this decision. This initial endowment consists of two parts:

- A monetary payment **to you**

- A monetary payment **to Operation ASHA**. 100% of this amount will be used to save human lives.

After you have received information about the initial endowment, you can make your choice between **Lottery A** and **Lottery B**.

Please note:

- The lotteries will change the monetary payments to you and/or the organization. You will learn exactly how the initial endowments will change if, for example, you choose Lottery A and the coin toss lands on heads.

- **Thus, how the monetary payments to you and the organization change depends both on which lottery you choose and the result of the coin toss.** The coin toss will be carried out by the computer.

Payments in this part of the study

All monetary payments in this part of the study will be made by bank transfer. In the following decision-making scenarios, monetary payments are made either to you or to the organization *Operation ASHA*. If you are the recipient, a bank transfer to your account will be made today. If *Operation ASHA* is the recipient of the monetary payment, a bank transfer to the organization's account will be made today. As previously explained, 100% of the amount

that is transferred to the organization's account will be used to save people from dying of tuberculosis.

In what follows, you will face a series of decision-making scenarios. One of these decision-making scenarios will be randomly selected by the computer at the end of this study. Your decision in *this* decision-making scenario will be implemented by a bank transfer at the end of this study. Your decisions in this part of the study thus determine *which* lottery is played at the end of this study.

Remember:

- Every decision-making scenario can be relevant for your monetary payment.

- Your decisions in this part determine both **to whom** the monetary payment will go and **at which date** the monetary payment will be made.

- All monetary payments will be made by bank transfer.

[**end of screen**]

Example

In the following decision-making scenarios, you can choose between **Lottery A** and **Lottery B**. On this page, we use an example to illustrate the choice between both lotteries.

In the following decision-making scenarios, you will see a page that looks like this:

On such a page, you will see information about the initial endowment, and how these endowments change depending on which lottery you choose and what the result of the coin toss is.

In the picture below, we explain the elements of this page in more detail:
In each decision-making scenario where you have to choose between **Lottery A** and **Lottery B**, we will show you an amount **X €**. The picture below illustrates what your decision would look like if $X = 10.00 €$. By selecting the left or right circle, you can choose between **Lottery A** and **Lottery B**.

To proceed click "Next".

[**end of screen**]

Exercise 1

On this and the following page, you can check whether you have correctly understood all the necessary information for this part of the study. For the first exercise, take a look at the following initial endowment:

The initial endowment for the following scenario:

- 25.00 € for you, and

- a donation of 25.00 € to the organization Operation ASHA.

In addition, you also have to choose between **Lottery A** and **Lottery B**.

Imagine that, given the initial endowment above, you had to make a decision between the following two lotteries:

- Lottery A:

  - If the coin toss is heads: the donation amount is reduced by 10.00 €.

  - If the coin toss is tails: the monetary payment to you is reduced by 10.00 €.

- Lottery B:

  - If the coin toss is heads: both the donation amount and the monetary payment to you are reduced by 10.00 €. You receive an additional **X** € as well.

  - If the coin toss is tails: you receive an additional **X** €.

  - $X = 2.00$ €

To test whether you have understood how your choice between Lottery A and Lottery B as well as how the outcome of the coin toss affects the monetary payments, please provide answers to the following questions:

- If I choose **Lottery A** and the coin toss is *heads*, the monetary amount that I will receive, including the initial endowment, is: [blank field] (in €)

- If I choose **Lottery B** and the coin toss is *heads*, the monetary amount that I will receive, including the initial endowment, is: [blank field] (in €)

- If I choose **Lottery B** and the coin toss is *heads*, the size of the donation, including the initial endowment, is: [blank field] (in €)

- If I choose **Lottery B** and the coin toss is *tails*, the monetary amount that I will receive, including the initial endowment, is: [blank field] (in €)

[**end of screen**]

Exercise 2

For the first exercise, take a look at the following initial endowment:

> The initial endowment for the following scenario:
>
> - 40.00 € for you, and
> - a donation of 0.00 € to the organization Operation ASHA.
>
> In addition, you also have to choose between **Lottery A** and **Lottery B**.

Some decisions involve a so-called **additional lottery**. Every additional lottery has a possible positive outcome (the monetary payment increases) and a possible negative outcome (the monetary payment decreases). The outcome of the **additional lottery** will also be randomly determined by the computer.

Note: Pay attention to the probabilities in the **additional lottery**.

Imagine that, given the initial endowment above, you had to make a decision between the following two lotteries:
- Lottery A:

    - If the coin toss is heads: the donation amount is reduced by 10.00 €.

    - If the coin toss is tails: There is an additional lottery for **your** monetary payment.

        * With a probability of 50%: You lose 14 €.
        * With a probability of 50%: You win 14 €.

- Lottery B:

  - If the coin toss is heads: the donation amount is reduced by 10.00 € AND you will receive an additional **X** € AND have an additional lottery for **your** monetary payment:

    * With a probability of 50%: You lose 14 €.
    * With a probability of 50%: You win 14 €.

  - If the coin toss is tails: you receive an additional **X** €.

  - $X = 5.00$ €

The additional lottery thus has a possible negative outcome of -14.00 € and a possible positive outcome of +14.00 €. Both outcomes are equally likely, that is, they both have a probability of 50%.

To test whether you have understood how your choice between Lottery A and Lottery B as well as how the outcome of the coin toss affects the monetary payments, please provide answers to the following questions:

- If I choose **Lottery A** and the coin toss is tails, then the outcome of the additional lottery is +14 €, and I will receive a monetary payment, including the initial endowment, of: [blank field] (in €)

- If I choose **Lottery B** and the coin toss is heads, then the outcome of the additional lottery is -14 €, and I will receive a monetary payment, including the initial endowment, of: [blank field] (in €)

[**end of screen**]

Your task begins on the next page

On the next page you will see the first decision-making scenario. From now on, the decisions you make are no longer an exercise, meaning that any of your following decisions and all related consequences could be implemented.

Remember:

- Every decision-making scenario can be relevant for your monetary payment.

- Your decisions in this part determine both **to whom** the monetary payment will go and **at which date** the monetary payment will be made.

- All monetary payments will be made by bank transfer.

To proceed click "Next".

D.3.1   RA–Self

The initial endowment for this decision is:

- 25.00 € for you, and

- a donation of 0.00 € to the organization Operation ASHA.

In addition, you also have to choose between **Lottery A** and **Lottery B**.

Both lotteries will be decided by a coin toss, which means that there is a 50% chance of heads and a 50% chance of tails.

[Description of the lotteries]

On the next page you will see a list where each row represents a different decision-making scenario between Lottery A and Lottery B. Each row indicates the value of **X** in that particular decision-making scenario. To proceed click "Next".

[end of screen]

Decision

The initial endowment for this decision is:

- 25.00 € for you, and

- a donation of 0.00 € to the organization Operation ASHA.

In addition, you also have to choose between **Lottery A** and **Lottery B**.

[Description of the lotteries]

Note: **X** € will be paid to you whenever you choose **Lottery B**, independently of whether the coin toss is heads or tails. Whether **X** is positive (a gain) or negative (a loss) depends on the decision-making scenario.

Lottery A ∘   ∘ **Lottery B** with **X = -5.00 €**
Lottery A ∘   ∘ **Lottery B** with **X = -4.50 €**
Lottery A ∘   ∘ **Lottery B** with **X = -4.00 €**
